been suggested (Meehl, 1950) that such circularity might be avoided if we emphasized the general, *trans-situational* properties of reinforcers. For example, if a given stimulus has been shown to increase the probability of a certain response in one situation, it should produce similar effects on other responses in new situations. Although trans-situational reinforcers do exist (for example, food for a food-deprived organism), there are many stimuli which prove to be reinforcers (1) of some but not all possible responses, and (2) in some, but not all situations. We are often made painfully aware of the dependence of reinforcing effects on the context in which they are applied. Saying "Good boy!" may be a potent reinforcer for the well-trained hound, but the sudden appearance of a bitch in heat may nullify the reinforcing effects of his master's voice. It is tempting to explain such changes as due to shifts in dominance within a hierarchy of "drives" or "motives," but similar changes occur as we go from home to schoolroom, from laboratory to playing field, and in these cases we have no independent means of identifying the drives that might be correlated with the reinforcers. Under such conditions, it does not seem that we can deny the existence of situational-specific reinforcers, and so we probably cannot insist on trans-situational properties in defining reinforcing stimuli. We thus are left with our simple behavioral criterion: Reinforcers are those stimuli which increase the probability of the response on which they are contingent. (See the discussion in Chapter 18 of the definition of drives in terms of reinforcers, pp. 796 ff.)

The theoretical role of reinforcing stimuli has been central to the attempts to subsume both classical and instrumental procedures under a single paradigm. For example, Hull (1943), suggested that all instrumental learning was based upon the action of reinforcers which were drive reducers, and raised the possibility that classical conditioning might involve the same processes. Inasmuch as the response in classical conditioning *follows* the *onset* of the unconditioned stimulus during at least the earliest phases of conditioning, the suggestion that drive reduction could account for classical conditioning never gained wide acceptance. Zeaman and his coworkers have examined classically conditioned changes in heart rate from the point of view of drive reduction, and have concluded that the relative lack of effects of varying the duration or intensity of the US provides strong evidence against the drive-reduction hypothesis. (See the survey in Zeaman and Smith, 1965.)

An alternative suggested by Guthrie (1935, 1952) interpreted both classical and instrumental procedures as variants of the conditioning of responses to stimuli through contiguity. As we have already mentioned, Guthrie[15] postulated the complete and instantaneous conditioning of each response to every stimulus present at the moment and argued that all training methods and conditioning procedures are merely techniques whereby the necessary temporal relations may be produced, and the resulting conditioning may be protected from eradication by subsequent conditioning. For example, given the problem of gaining control over a response R_A, we might passively await its occurrence or try to elicit it through manipulation of stimuli; at the same time that the response is occurring, we would seek to have present some set of stimuli (S_1) which we can control. Once there is an occurrence of R_A in the presence of S_1, the response becomes (according to Guthrie) completely conditioned to S_1. However, because behavior never is abruptly terminated, other responses may follow R_A, and if we have failed to terminate S_1 as soon as R_A occurred, these other responses will, as each occurs, become conditioned to S_1 and each, in turn, will displace its immediate predecessor. Thus, temporal contiguity not only will condition R_A to S_1 but, if we allow S_1 to continue, will condition interfering responses to S_1.

In situations where we cannot exercise adequate control over the stimuli, a some-

property by stating that it is a reinforcer. If we stop with the definition, we are classifying the stimulus but not explaining the property. At present, there is no satisfactory explanation that applies to all instances of reinforcement.

[15] Guthrie did not attempt to provide a set of formal statements summarizing his theoretical position. One set of postulates consistent with his theory has been presented by Voeks (1950). For a concise statement of a contiguity theorist's interpretation of the role of reinforcing stimuli, see Sheffield (1965).

what different problem exists. Suppose we have managed to obtain the contiguous occurrence of S_1 and R_A, but the nature of the response is such that it must occur in bursts; if the stimuli vary during the burst of R_A responses, whatever is the stimulus set present when the last R_A occurs will be its controlling stimulus.

Of course, we know from both practical experience and laboratory investigation that reinforcement and punishment are effective in modifying and maintaining behavior, but Guthrian contiguity theory denies the necessity of these factors, and explains their effectiveness by referring to the manner in which they change the stimulus situation or the response pattern. Why does a single delivery of a food pellet greatly increase the probability that the response that is just being made will reoccur? Because, says Guthrie, the food pellet changes the stimulus situation from what it was just as the response occurred and (by drawing the animal toward it and away from the place where the response was made) insures that the response cannot become conditioned to a different set of stimuli. A similar analysis is offered for the roles of aversive stimuli and their terminations: The burned child withdraws his hand from the flame, thereby insuring that withdrawal is the last response made in the presence of the flame. Hence, the very next presentation of the flame should produce the withdrawal movement.

This interpretation of the role of reinforcers implies that if the subject is promptly removed from the environment in which a response is made the response just conditioned will not suffer any interference from conflicting conditioning. "Removal" from the environment would desirably be accompanied by changing all the stimuli impinging on the organism—a practical impossibility, of course, since many of our stimuli are the products of relatively steady bodily states. However, if effective removal does immediately follow a response, and if the subject is later reintroduced to that environment, that last response should again be made. Whether such effects have indeed been demonstrated under controlled laboratory conditions is a moot point. Some indirect evidence is provided by a study of one-trial avoidance behavior (Hudson, 1950; see also Tolman, 1948, pp. 200-201). Hudson equipped a chamber with a food cup and a distinctive striped wall panel. Rats were used as subjects and electric shock was delivered to some of them when they touched the food cup; at the same moment, the chamber was completely darkened, and the food cup and the pattern were removed. The lights were then turned on again, and the animal was removed from the apparatus. When the rats were returned to the lighted chamber the next day, many (but not all) repeated the last response they had made in that situation: They approached the striped pattern and touched the food cup. This result is exactly what Guthrie would have predicted—although it is difficult to see how he would have accounted for the many other types of reactions that also occurred. For example, some animals later avoided the cup, while others seemed to be avoiding other areas of the chamber. Because the lights were turned off and the striped pattern and cup were removed at the instant the shock occurred, it is difficult to imagine that any response other than approach could have been the last response made in the presence of the cup and stripe stimuli. This is an intriguing problem which certainly deserves additional investigation.

The results of a study of removing the subject from the situation in which no aversive stimulation was employed also are rather equivocal so far as contiguity theory is concerned. Seward (1942) compared the effects of three treatments, removing each rat from the apparatus as soon as (1) a bar press had been emitted, (2) the animal had seized the food pellet delivered when he pressed the bar, or (3) one minute had passed. Mere removal following the bar press was less effective than food reinforcement, but more effective than noncontingent removal, in terms of the latency of the first response on each training day and the number of re-

sponses emitted on extinction tests. Perhaps as interesting as these results was Seward's observation that eight of ten animals removed following the bar press response also learned to "anticipate" removal: "They approached the bar, pressed it with a forefoot, quickly swung around, sometimes looking up at the experimenter, and waited motionless a second or two" (p. 254). Again, this is what Guthrie might have predicted, but that the behavior was conditioned by contiguity and protected by removal from the chamber is impossible to prove, because there is always the possibility that reinforcement of some kind was present (for example, in the procedure of handling the animals, which so frequently in their lives has been paired with feeding).

In summary, Guthrie suggested that the basic unit of learning was the association of response and stimulus, based solely upon their contiguous occurrence, with reinforcing stimuli aiding the process by protecting what had already been accomplished by contiguity. This theory differs from usual interpretations of instrumental learning in that it denies the necessity of reinforcement. It differs from the usual interpretations of classical conditioning by maintaining that the association is between stimulus and response, rather than between two stimuli.

We have reviewed these theories because the basic ideas are still to be found in contemporary theorizing and, in at least some cases, are more easily understood in the simpler forms of an earlier generation. At the present time, many writers feel that some variety of two-factor theory is needed to account for the differences produced by the classical and the instrumental procedures. Representative two-factor theories have already been mentioned (p. 563); for an evaluation of the applicability of this point of view to avoidance learning, see Rescorla and Solomon (1967).

Experimental Extinction

The second of Pavlov's major contributions to the understanding of learning processes was the discovery of experimental extinction. Perhaps "discovery" is an inappropriate word, for the general idea of extinction—like that of conditioning—was well known in folklore, even if the philosophy of Associationism had never given it formal recognition. But it is a long step from knowing that the villagers eventually will cease to respond if one repeatedly cries "Wolf!", to the specification of the conditions under which the process will occur. Moreover, the facts of experimental extinction seemed to run counter to the Associationists' Law of Frequency, which made the "discovery" of extinction that much more difficult.

Extinction sometimes is treated merely as a technique for the elimination of previously conditioned responses. Such impressions miss the signficance of the phenomenon: Extinction does not involve a simple unstacking of the associations built up through conditioning; it is an active process in which something new is learned about the environment.

The paradigms for extinction always assume prior classical conditioning or instrumental training. Given that, the paradigms are:

Following Classical Conditioning	*Following Instrumental Training*
Present CS; omit US	Omit reinforcing stimulus

In the classical situation, the experimenter controls the spacing of extinction trials, and although the subject sometimes makes responses between trials in the absence of the CS, for the most part the intervals between trials can be manipulated to suit the purposes of the experiment. The same is true of those instrumental situations in which trial-by-trial procedures are employed. However, in many cases, the "free operant" technique is the procedure of choice, and then the rate with which responses are emitted is the primary datum and the experimenter strives to avoid any contamination of this rate by arbitrary divisions of the observation periods. This matter of technique becomes important when the spacing of responses in extinction is considered (see pp. 576–577; and Figure 14.3).

In all important respects, extinction following classical conditioning and following instrumental training appears to be the same general phenomenon, and there has thus far been no need to construct any "two-factor" theories of extinction.[16] Considering the differences between the two situations, it is somewhat surprising that this is so. If, for example, classical conditioning is basically an association of two stimuli, and the instrumental procedure is one which generates an association of a response and a stimulus (that is, the reinforcer), we might expect different effects, different important parameters, different functional relations to obtain in the two cases when we break the correlation between the paired terms. This is not the case. The same kinds of effects seem to be found in extinction following both procedures.

We are indebted to Pavlov for the description of the basic phenomena associated with the omission of the US.

Briefly, the major ones are:

Extinction—Pavlov used the term to refer both to the *procedure* of omitting the US and to the *result* of the procedure, which usually was continued until the first trial on which no CR occurred. At that point, it was said that extinction was "complete."

Spontaneous recovery—after a pause in the extinction procedure, an increase in the CR may be seen.[17]

Disinhibition—if a novel stimulus is introduced during or immediately following extinction trials, an increase in the CR may be seen.

Reconditioning—if extinction trials are followed by a single presentation of the CS-US combination, much or all of the effects of extinction will be overcome.

Differentiation—if one stimulus is paired with the US and another stimulus is not paired with it, the former will become a CS and the latter will not.
Figure 14.3. Extinction with massed and spaced extinction trials. Subjects were conditioned with an auditory CS and air puff US; the response was the eyelid closure to CS. These results are for subjects conditioned with a 450 msec CS-US interval, with 1-2 min between trials. Spaced extinction trials had 1-2 min intertrial intervals; massed extinction had 10-20 sec between trials. Note that there was a change in intertrial interval for subjects in the massed extinction group, which might (through generalization decrement) produce some difference between the groups. At least, this has been suggested as an explanation for some of the failures to find massed extinction to be more rapid than spaced extinction where instrumental behavior is involved (Teichner, 1952). In Reynolds' experiment, other groups conditioned with massed trials and extinguished either with massed or with spaced trials showed little difference during extinction. This could be taken as partial support for Teichner's hypothesis, if we assume that the spaced groups in this instance had response decrements due to changes in intertrial intervals, thus canceling the "normal" difference between massed and spaced extinction procedures. (After Reynolds, 1945.)

[16] For example, the major phenomena observed in salivary conditioning also seem to be demonstrable in conditioned fear experiments (Maier, Seligman, & Solomon, 1969). For a summary of Pavlovian and instrumental procedures using aversive stimulation, see Chapter 16.

[17] Pavlov said, "Left to themselves extinguished conditioned reflexes spontaneously recover their full strength after a longer or shorter interval of time, but this of course does not apply to conditioned reflexes which are only just in process of formation. Such reflexes, being weak and irregular, may require for their recovery after extinction a fresh reinforcement by the underlying unconditioned reflex. However, all those conditioned reflexes which have been fully established invariably and spontaneously return sooner or later to their full strength" (1927, p. 58). Laboratory studies (including those of Pavlov) rarely show complete recovery, suggesting that he considered such conditioned reflexes to be less than "fully established." See Ellson (1938) and Homme (1956).

TABLE 14.2 INTERFERENCE THEORY INTERPRETATIONS OF "HABIT BREAKING"

Name	*Procedure*	*Explanation*	*Examples*
1. Exhaustion method	Present CS continually until CR no longer occurs (as a result of fatigue, exhaustion, etc.)	Although CR ceases, CS is still present and whatever other responses now occur are conditioned to CS	Typical experimental extinction procedure; bronco busting
2. Incompatible response method	Present CS while also presenting stimuli which control responses that are incompatible with CR	Since CR is "blocked" by other responses, and these are made in presence of CS, CR is displaced as the reaction to CS	Counterconditioning therapy (e.g., present to male homosexual a picture of a man, and then present electric shock)
3. Toleration method	Present CS in a weakened or disguised form; gradually bring CS back to original condition	By greatly modifying CS, occurrence of CR is avoided; by gradually changing CS, whatever other responses had been occurring to altered CS will continue to occur	Halfway-house techniques (e.g., gradual introduction of some of the cues that in the past have produced aberrant behavior); gentling procedures; seductions

In these phenomena we see some of the reasons why extinction cannot be thought of merely as an undoing of prior conditioning. For example, if that were a sufficient interpretation, then there should be no spontaneous recovery. For the same reason, extinction cannot be considered to be the conditioning of some other response that blocks the original CR, for conditioning is relatively permanent and its effects would not be expected to dissipate spontaneously to allow the recovery of the first CR. Neither should a single reinforcement of the extinguished CS (that is, reconditioning) bring it back to such strength if extinction were a matter of conditioning incompatible responses. Finally, there is the important point that conditioning usually progresses best when trials are broadly spaced (see, for example, Schlosberg, 1934), while extinction effects usually are most readily obtained when trials are massed (Figure 14.3).

Interference theories The observations discussed above seem to offer serious difficulties for theories such as those proposed by Guthrie (1935, 1952) and Wendt (1936), which hold that extinction and conditioning are really a single process. Guthrie countered such arguments by maintaining that many instances which are labeled "extinction" really should be called "habit breaking" and that they are quite clearly situations in which one response is replaced by another.

Guthrie described three types of situations that he felt would include the bulk of the classical and instrumental procedures that usually are categorized as "extinction." In each, the key to successful replacement of the unwanted response involves a recombination of stimuli and responses, so that new responses become conditioned to the old stimuli, and vice versa. Guthrie's suggestions are summarized in Table 14.2. Whereas everyday examples of these procedures are quite common, few studies have examined the techniques under carefully controlled conditions.

In what must have been one of the first investigations of behavior therapy techniques, Mary Cover Jones (1924) examined the efficacy of procedures designed to eliminate children's fears. In one such test, the child was placed in a high chair and given something to eat. The feared object then was introduced

TABLE 14.3 COMPARISON OF "TOLERATION" AND "EXHAUSTION" METHODS OF ELIMINATING RESPONSES

	Mean number of extinction responses				
Group	*In 16 min of toleration procedure*	*In 30 extinction trials*	*Total*	*Opportunities for responding*	*Mean Rs/op*
Toleration	1.1	5.4	6.5	92	.07
Exhaustion	—	14.4	14.4	30	.48

From Kimble & Kendall, 1953

at a distance. While the child was eating, the object was brought slowly toward him, until finally it could be placed next to him or close enough to be touched, without fear responses having occurred. Note that this procedure involved a combination of gradual introduction of the feared object (Case 3) and simultaneous elicitation of a behavior (eating) that was incompatible with fear (Case 2), and that it was essential to adjust the rate of approach of the feared object so that eating was not completely disrupted, for this might have had the undesirable effect of making food the CS for emotional reactions.

The toleration technique was compared with the more usual extinction procedure (Case 1) by Kimble and Kendall (1953). First, laboratory rats were given 60 trials of avoidance training, using a light as CS and foot shock as US. The CS came on 5.8 seconds before the shock. The compartment contained a wheel which would terminate both CS and US if rotated by the rat. If the wheel were turned during the preshock interval, the CS went off and the shock was cancelled. Thus, the rat could avoid all shocks by turning the wheel within 5.8 seconds after the light was turned on.

Following this avoidance training, one of two types of treatment was used. One group received typical experimental extinction: on each of thirty trials, the CS came on for 15 seconds or until the rat turned the wheel. The second group was exposed to seven "toleration" trials, in which the CS intensity was increased every 15 sec, starting at a brighter value each trial. At the end of each trial, it was as bright as it had been during training (and, of course, as the other group's CS had been throughout). Once the light was turned up to this level, thirty trials of regular extinction were given. The results are summarized in Table 14.3. Note that the toleration procedure was effective: The rats in the toleration group made very few wheel-turning responses during the extinction phase.

Because spontaneous recovery usually follows typical experimental extinction procedures, we might expect the animals in the exhaustion group to make many responses if they were placed in the apparatus again on the following day. In contrast, Guthrie's theory would predict that the animals in the toleration group would show relatively little spontaneous recovery. There does not seem to be any published data on this problem, but were this to be the case, we could count the toleration procedure superior as a technique for both immediate and for long-term behavior modification.

Why does the typical extinction procedure have the effect of reducing the strength of the CR? Guthrie suggested that the first omission of the US (or of the reinforcing stimulus, in operant situations) creates a major change in the stimulus situation, both directly and indirectly, through feedback from the resultant excited or agitated behavior. If the next trial follows soon afterward, the CS might be expected to be lost in this mass of changed stimuli, and so a lowered probability of the response would be predicted. With time, the excitement or agitation should pass, the stimulus situation should become more similar to the earlier conditioning situation, and therefore spontaneous recovery might be expected.

Applied to extinction problems, contiguity

theory would seem to imply that very widely spaced extinction trials would not result in any decrement in the CR, for if we remove the subject from the experimental situation immediately following the response, we should "protect" the conditioning and make the extinction trial the equivalent of another training trial. However, extinction *does* occur when trials are spaced as much as one a day (Weinstock, 1964). Contiguity theory accounts for this apparent contradiction by assuming that the omission of the reinforcing stimulus on the first extinction trial immediately causes marked changes in behavior, and these new responses are, of course, immediately conditioned to the stimuli present at that moment.

Consider the simple running response of an animal placed in a straight alley. On the first extinction trial, the animal approaches the portion of the goal box where food previously had been placed; there being none, he now emits other responses (standing up, jumping, and so on) which are immediately conditioned to apparatus stimuli and which, on the next trials, interfere with swift running. Such responses become conditioned to greater proportions of the stimuli on succeeding trials, thus generating the familiar extinction curve.

Such new and potentially interfering responses do occur on extinction trials, but the extent to which they are incompatible with the previously reinforced responses is difficult to estimate. Adelman and Maatsch (1955) maximized the differences in such behaviors during extinction by allowing one group of rats to retreat from the goal box into the alleyway, allowing another group to leap out of the goal box onto its upper edge, but giving a third group the "normal" treatment of confining the rat briefly in the empty goal box. The "jump" group showed almost no extinction of the response of running in the alley, whereas the group allowed to "recoil" into the alleyway extinguished more rapidly than the "normal" group. These results are interpreted as support for interference theory because the "recoil" response is thought to be most incompatible with forward locomotion in the alley, and the "jump" response is said to be compatible with forward locomotion (see also Weisman et al., 1966). Quantifying the degree of incompatibility of responses is an obvious next step for the proponents of such hypotheses.

Inhibition theories Pavlov assumed that activity of the nervous system could be categorized as either excitatory or inhibitory, with the former being associated with the occurrence of reflexes and the latter with their nonoccurrence. He postulated several types of inhibition. On some occasions, the sudden appearance of a novel stimulus may disrupt a CR; Pavlov assumed that the stimulus must have initiated an inhibitory process which, because it was associated with changes in the external environment, he labeled *external inhibition*. Such effects typically are maximal on their first occurrence and diminish with repetition. *Internal inhibition* was assumed to be generated whenever the CS is presented: "The cortical cells under the influence of the conditioned stimulus always tend to pass, though sometimes very slowly, into a state of inhibition. The function performed by the unconditioned reflex after the conditioned reflex has become established is merely to retard the development of inhibition" (Pavlov, 1927, p. 234). If the CS is regularly presented for many seconds (for example, 30) before the US, *inhibition of delay* (another form of internal inhibition) is built up, and the CR occurs later and later after the onset of the CS. If, however, the US is omitted altogether, inhibition develops with greatest rapidity, and extinction is observed. Even when CS and US are paired, if the pairings are closely massed, or if they are continued for weeks or months, gradual diminution of the CR may occur (*inhibition of reinforcement*: see Hovland, 1936; Kantrow, 1937). Inhibition, like excitation, is subject to disruption; introduction of an external inhibiting stimulus during a long CS, or during extinction trials, may result in the immediate reappearance of the CR (interpreted as inhibition of internal inhibition by external inhibition, or *disinhibition*).

From the point of view of theory construction, it is interesting to note that none of these inhibitory processes were directly observed; they were instead inferences from observations of behavior. Many psychologists have found the hypothetical physiological processes attached to the concepts not very helpful and have therefore discarded them, while keeping the functional aspects of these or similar notions. For example, Hull (1943) postulated an inhibitory factor, *reactive inhibition*, which (1) was generated whenever a response occurred, and which (2) dissipated spontaneously with the passage of time. Furthermore, he assumed that (3) the more work that was involved in the execution of the response, the greater the increment of reactive inhibition per response. With reactive inhibition given these properties, it could be used to deduce such phenomena as selection (other things equal) of the shorter path or the response that requires the least effort (the "Law of Less Effort"; see Thompson, 1944; Solomon, 1948); more rapid conditioning with spaced trials and more rapid extinction with massed trials; spontaneous recovery of extinguished responses; and reminiscence following massed practice.

However, because spontaneous recovery rarely is complete, and because a consistent use of closely massed trials leads to poorer conditioning than does the use of more widely spaced trials, Hull postulated a more permanent form of inhibition, *conditioned inhibition*. In essence, this was conceived to be a learned response of not responding; as a learned response, it had (according to Hull's theory of reinforcement) to be reinforced by drive reduction, and so reactive inhibition was given the property of being an aversive drive, thus making its dissipation reinforcing. The occurrence of several effortful responses in close succession would, according to this theory, produce an accumulation of considerable reactive inhibition, which would begin to dissipate when the response was not made (that is, the subject was either "resting" or making some other responses), and this behavior of not responding (the conditioned inhibition of the response) would therefore be strengthened. Being a learned response, conditioned inhibition would acquire its habit strength gradually; it would generalize to similar stimulus situations, and otherwise
Figure 14.4. Massed and spaced practice on a pursuit rotor. The subject's task was to keep a stylus tip on a small target as it rotated at 78 revolutions per minute. The response was recorded as the amount of time during each trial that the stylus was on the target. Our curves here are smoothed within each day except for the first, second, and last trials of each day; these are shown separately to bring out the following features: (1) the rapid rise in proficiency shown by the jump from Trial 1 to Trial 2 on each day, usually thought to be due to a "warm-up" effect or reinstatement of the appropriate modes of response; (2) the decline in proficiency within daily sessions shown by the massed practice group; (3) the recovery from this decline; and (4) the overnight loss after a day of rising scores. In spite of the complications introduced into the curves by warm-up and work decrement, the general course of learning can be seen. The second trial of each day is least affected by these complications; drawing an imaginary curve through all of the Trial 2 points shows that the massed practice group is already falling behind after two days of practice. As long as conditions remained unchanged, the spaced practice group would probably continue its superiority; if conditions were interchanged for a few days, the groups might reverse their positions. (After Kimble & Shattel, 1952, as modified by Woodworth & Schlosberg, 1954.)

would show the properties of habits in the Hullian system.

> This form of inhibition theory has been most thoroughly developed and applied in the interpretation of "massed" versus "spaced" (or "distributed") practice (Ammons, 1947; Irion, 1966). For example, Kimble and Shattel (1952) gave college students the task of learning to keep a stylus on a rotating target ("rotary pursuit"), where the score is the time per trial that the stylus tip is on the target. Two groups of subjects were run, each subject receiving 15 trials a day for 10 days, with each trial lasting 50 seconds. The group that had been given massed practice was allowed a 5 to 10 sec pause or rest between trials, while the group that was given distributed practice had 65 to 70 sec between trials. The average scores for the two groups are shown in Figure 14.4. Note that both groups became increasingly proficient with practice, but that the superiority of the spaced-practice group increased as the experiment continued, a result attributed to the greater amount of conditioned inhibition acquired under the massed practice conditions.
>
> The rapid increase in proficiency following a period of no practice has been attributed to the dissipation of reactive inhibition. Such gains in performance associated with "resting" are called *reminiscence effects,* and frequently are quite large in situations involving motor skills. They are not merely a result of recovery from fatigue in the limbs used in making the skilled responses. Subjects can be asked to practice using one hand and then shift to the other hand. Those forced to wait a few minutes before beginning the bilateral test perform better than those who are given no such pause in the schedule (Grice & Reynolds, 1952; Irion & Gustafson, 1952; Kimble, 1952). Adams (1955) showed that some of the inferior performance of subjects allowed no rest in such bilateral transfer studies might be associated with the perceptual side of the skilled behavior. He required some subjects to devote the periods during which they were not practicing to close observation of the performance of other individuals. When they resumed practice, such subjects showed less reminiscence than did those who received the standard type of treatment (that is, "rest") during the pause. Such results showed that reminiscence could not be attributed merely to dissipation of an inhibitory factor which was presumed to be localized in effectors.
>
> These experiments were among the last of the several score of studies that were largely prompted by Hullian inhibition theory and which appeared during the decade following the publication of *Principles of Behavior* (Hull, 1943). On the whole, good progress had been made toward specifying conditions under which temporary and permanent decrements in performance would be found, but it seemed that each new experiment required an additional amendment to the properties ascribed to reactive and conditioned inhibition. Eventually, enthusiasm for such research just seemed to evaporate.
>
> Of course, there are fads and fashions in research just as in other areas of human endeavor, but more than this is needed to explain the very rapid disappearance of experiments directed toward Hullian inhibition theory. Underwood (1966) suggests that one factor might have been the growing recognition that these concepts had relatively little to contribute to some of the key problems in verbal learning. At the same time, the emphasis in much of animal learning was shifting toward the use of free operant techniques, where—by releasing the responses of the subject from direct control and making response rate a dependent variable—the experimental study of Hullian-type inhibitory effects becomes exceedingly difficult. Finally, the newest trends in learning—quantitative models, short-term processes, analysis of behavior changes in the individual organism, and the physiological and anatomical investigations—all took attention away from Hullian inhibition theory.
>
> Inhibition theory may be just temporarily in the doldrums, awaiting some new ideas and experimental techniques. However, the concept of conditioned inhibition has become so encumbered by *ad hoc* properties that it probably will not again be as widely employed as it once was. (For a critique of these concepts, see Underwood, 1953; Gleitman, Nachmias, and Neisser, 1954. For a survey of experiments on massed versus spaced practice, see Woodworth and Schlosberg, 1954, pp. 786–794.)

In several important respects, Hull's intervening variables of reactive and conditioned inhibition differed from Pavlov's hypothetical inhibitory process. For example, Pavlov concluded that all inhibition, regardless of its origins, was of one type; that it was an inherent protective activity of the cerebral cortex; and that it was associated with the presentation of stimuli, and, in conditioning, especially with the presence of the CS. Hull, as we have

seen, postulated two quite different forms of inhibition, the one associated with effector activities and the other with learning to withhold a response. In general terms, it might be said that Pavlov's ideas about inhibition revolved around the hypothetical mechanisms of the cerebral cortex which protect it from repetitive and interruptive stimulation, while Hull's thoughts on inhibition concentrated on the response mechanism and the adaptive habits of resting or of varying responses.

Before leaving the topic of inhibition, we should mention still another way in which it is used. Just as the physiologist finds the terms *excitation* and *inhibition* to be useful ones with which to refer to processes associated with activity, on the one hand, and the lack of activity, on the other, so have behaviorists found these terms convenient to describe parallel changes in responding. Furthermore, just as there are numerous mechanisms which may produce excitatory or inhibitory consequences at the levels of cells, tissues, and organs, so there may be many ways in which behavioral outcomes of an excitatory or inhibitory nature may be effected. For example, both nonreinforcement (that is, extinction) and punishment of a response will decrease its probability of occurrence, and therefore both procedures could be said to generate inhibition of that response.[18] It is in this descriptive sense that inhibition was used by Spence (for example, 1936) and others to describe the consequences of nonreinforcement in discrimination learning (see pp. 764; and 770 ff.).

[18] Punishment (see Chapter 16) generates "passive avoidance" behavior, with mere withholding of responding being sufficient to avoid aversive stimuli. In many other situations, "active avoidance" is required if the aversive stimulus is to be avoided. Typical active avoidance responses used in the laboratory are jumping into a "safe" compartment of a shuttle box, or pressing a lever or panel. McCleary (1961) has demonstrated that passive avoidance behavior in cats is diminished or destroyed when lesions are placed in the subcallosal cortex and adjacent septal region of the brain, while active avoidance remains unimpaired by such damage. For this reason, these areas have been called "inhibitory areas" for avoidance behavior, since the ability of the cat to inhibit the emission of a response which will be punished is much diminished when bilateral lesions are placed in such regions.

Spacing of extinction trials In operational terms, extinction is the omission of reinforcement. If every response has been reinforced, the first omission of reinforcement frequently is followed by recognizable signs of disturbance, often identified with "frustration." One of the attributes of this frustration reaction is an increase in the vigor of whatever responses are occurring at the moment. As a consequence, there may be a period during which the previously reinforced response shows an increase in vigor and/or rate of occurrence when extinction is first introduced. For example, if a rat has found food in the goal box of a straight alley (Figure 15.1, p. 618) on every previous trial, on the first occasion when he does not find it he may show overt agitation, be difficult to handle, jump about in the goal box, and so on. If he then is placed directly into the start box and the next trial is initiated, the excitement caused by the frustration may cause the rat to run even faster than during reinforced trials (see Amsel, 1958; Wagner, 1959).

Now, in such situations, closely massing the extinction trials keeps activity at high levels and increases the number of extinction trials needed to attain an extinction criterion, whereas spacing the extinction trials allows the excitement to diminish, with the consequence that running becomes slower and extinction criteria are met in fewer trials (Sheffield, 1949). Such effects of "frustrative nonreward" are likely to be found wherever the response measure is one which is enhanced by excitement. That it does not represent a contradiction of Pavlov's general rule (that is, extinction is faster with massed than with spaced trials) has been demonstrated most clearly by Stanley (1952), who showed that massing extinction trials slows down the extinction of running responses while it speeds up the extinction of the response of turning into the formerly reinforced side of a T maze. Hence, we must qualify our general rule about extinction and the spacing of extinction trials: For responses that are not augmented by increased overall excitement, the

number of trials to extinction is positively correlated with the time between trials; for responses that are augmented by excitement, the number of trials to extinction is negatively correlated with the between-trials interval.

How can we summarize the simple facts about extinction? First, it is not a mere cancellation of the effects of reinforcement, else spontaneous recovery would not occur. Next, it is (like other learned reactions) sensitive to distractions, as shown by Pavlov's "disinhibition." Furthermore, it shares with other learned reactions the phenomenon of stimulus generalization: If a response is extinguished in the presence of one stimulus, varying the stimuli along some dimension will diminish the extinction effects in proportion to the amount of stimulus change between extinction and testing (Kling, 1952; Honig, 1961). Finally, extinction procedures may generate considerable excitement which in some cases may increase the vigor of responding, while in others it may interfere with the emission of previously reinforced responses.

Sensitization

Ordinarily, when we discuss the definition of learning, we mention certain modifications of behavior that are said to be artifacts of the methods of experimentation rather than instances of "real learning." *Sensitization* and *pseudoconditioning* are the two most frequently mentioned "artifacts." They are especially likely to be encountered in conditioning studies involving aversive stimulation; they are said not to be instances of true conditioning because they do not depend upon pairing of the conditioned and the unconditioned stimuli. The implications of this statement will be better appreciated when we examine the phenomena themselves. Let us look first at sensitization.

In a typical classical conditioning experiment, we assume that the experimenter has satisfied himself that the stimulus to be used as the conditioned stimulus is neutral so far as the response to be conditioned is concerned. However, there are some responses which can be elicited by a very broad range of stimuli; with such responses, it is possible that the to-be-conditioned stimulus is, in fact, itself an unconditioned stimulus. But how could an experimenter be unaware that his conditioned stimulus was not neutral? Imagine that the intensity of an unconditioned stimulus be reduced to the point where it does not quite elicit the unconditioned response, and further, that our experimenter is unfortunate enough to have selected this stimulus *at this intensity* for his conditioned stimulus. On testing, the stimulus would appear neutral. Now imagine that circumstances exist which somehow make the organism more sensitive to the stimulus, so that the response to it will occur even though the intensity of the stimulus remains at what previously had been a "subthreshold" level. If this were to happen during the experiment, responses to the "neutral" stimulus would begin to occur and might easily be mistaken for conditioned responses.

An example of this type of effect can be seen in a study by Prosser and Hunter (1936). As part of a series of studies on the conditioning of spinal reflexes, they presented auditory stimuli (clicks) followed by electrical shocks of the hind limbs. After pairing click and shock a number of times, the click alone elicited the hind limb responses. At this point, less astute experimenters might have accepted the behavior as evidence of classical conditioning and gone on to the next problem. Prosser and Hunter, however, were made suspicious by the constancy of the latency of the "CR" across trials, for ordinarily there is a latency difference between CRs and URs (Hunter, 1937; see also Fig. 14.1). Eventually they concluded that the shock raised the excitability of the neural "centers" involved in the reaction to the click, so that the previously ineffective clicks could become—and remain—capable of eliciting the limb movements.

This, then, is the general line of reasoning followed whenever the behavior change is

imputed to sensitization: The CS is not neutral, but merely ineffective under present conditions, and the US (or other aspects of the procedure) either heightens excitability or shifts the response bias (see p. 37) of the subject so that responses to the CS now occur.

Similar effects were noted by Sears (1934). He found that in his experimental conditions, presenting a light to goldfish caused them to swim excitedly. Repeated presentations of the light produced a waning of the response, but isolated shocks (that is, shocks not paired with the light) reinstated the response to the light—and to other stimuli (for example, vibration) as well. This same phenomenon may underly some of the "learning" which has been observed in the headless cockroach and other surgically isolated preparations (see, for example, Horridge, 1962; Eisenstein & Cohen, 1965; Pritchatt, 1968; and Kling & Stevenson, in press).

In such experiments, the UR and the response elicited by the supposedly neutral stimulus may be identical, or they may be so similar that they easily can be confused. This is a highly probable state of affairs if the behavior to be measured is gross activity, or startle responses, or components of the orienting reflex. One of the experimenter's best defenses against mistaking sensitization for conditioning lies in the selection of a response to be conditioned that cannot be confused with one of the preconditioning reactions to the CS. Where this is not possible, control groups must be run which do not have CS and US paired in presentation, and comparisons of the level of responsiveness shown by experimental and control groups must be used to estimate the level of unconditioned behavior attributable to sensitization (see, for example, Bitterman, 1964).

In brief, "sensitization" implies that the reactivity of the organism *to the CS* has been increased by presentations of the US, and that the CS never was originally neutral.

Pseudoconditioning The classical study of pseudoconditioning is that of Grether (1938). While studying the acquisition of emotional reactions, Grether developed a technique for restraining his rhesus monkeys in a chair and eliciting the characteristic fear response with a sudden, explosive US. His CS was an electric bell, and in preliminary tests he had found the bell to be quite neutral so far as the fear response was concerned. Two monkeys were "conditioned" by presenting the US, followed 3 seconds later by the CS; after ten of these trials, the CS alone elicited the fear reaction. Grether did not accept this evidence for backward conditioning at face value, but instead adapted two more monkeys to the procedure and trained them with ten presentations of the US alone. When the CS, *or any other sudden noise* was presented, the characteristic fear response was emitted. On the following day, the bell still caused the fear

TABLE 14.4 COMPARISON OF PARADIGMS FOR SENSITIZATION, PSEUDOCONDITIONING, AND CONDITIONING

	Sensitization		*Pseudoconditioning*		*Conditioning*	
Phase	*present*	*observe*	*present*	*observe*	*present*	*observe*
Preliminary tests	"CS" US	? UR	CS US	? UR	CS US	? UR
Experimental procedure	US	UR	US	UR	CS-US	CR & UR
Final test	"CS"	UR	Any novel stimulus	UR	CS	CR

reaction when the monkeys were brought into the experimental room and placed in the chair, but outside this room, the bell was "neutral." Thus, it is reasonable to assume that the cause of the heightened excitability that allowed the bell or any other noise to set off the fear reaction was partly in the experimental room itself (that is, in the "contextual stimuli" provided by apparatus, restraining chair, and so on) and not just in the "CS" alone. In this sense, Grether's description of the behavior as "pseudo-conditioning" was especially apt, for there was no evidence that the bell acquired any new properties as a result of pairing with the US.

The paradigms for sensitization and pseudoconditioning are very similar to those for conditioning (see Table 14.4), and it is not surprising that the earliest studies of conditioning using aversive stimuli did not include appropriate safeguards against these artifacts. The basic difference between the two artifacts is that sensitization occurs because a stimulus is used which is not neutral under all possible conditions of the experiment, whereas pseudoconditioning involves no such special reflex, but does introduce a state of affairs in which any sudden or novel stimulus will elicit a response which cannot be distinguished from the UR. Almost always these are complications that must be suspected to exist when we are using stimuli which cause emotional upset, and almost certainly one or both can account for most or all of the reported instances of backward conditioning (see p. 557). At least, since awareness of these problems and the use of appropriate control groups has become increasingly widespread, there has been a noticeable dearth of claims for backward conditioning!

Examples of the use of such control groups may be found in the experiments of Mowrer and Aiken (1954) and Matsumiya (1960). They were studying the effects of CS-US relations on the acquisition of fear responses (see p. 719) by noting how much suppression of food-reinforced bar pressing occurred when a CS which had been paired with shock was introduced into the bar-pressing session. If the CS had acquired strong fear-producing properties, bar pressing should be markedly suppressed, but the very same effects could be caused by sensitization and pseudoconditioning. Sensitization might be expected because the stimuli used as CSs (flashing lights and buzzers) could conceivably elicit some fear reactions if prior foot shock made the animals more sensitive to these stimuli. Pseudoconditioning might occur because the emotional upset created by the foot shock could be triggered by any sudden change in stimuli, as when the CS is introduced into the test session. Hence, these experiments included control groups in which the CS and US were presented with several minutes between them, to preclude any conditioning. During the test session, animals in such control groups did show some suppression, but the amount of the effect was small and short-lived as compared with the effects seen among those animals who experienced CS-US pairings (see Figure 16.10, p. 718).

Exposure Learning

This phenomenon, which seems to be distinctly different from the effects of either the classical or the operant procedures, has sometimes been called "perceptual learning," although the term "exposure learning" is currently in greater favor because it seems to be less restrictive in its implications. The paradigm for exposure learning may be summarized in this manner:

1. Expose subjects to stimulus.
2. Test, using stimulus as S+ or S− in discrimination problems.

The assumption underlying the use of discrimination tests is that if mere exposure of the stimulus has had any effects at all, it will be more readily discriminated than some stimulus to which the subject has not been exposed.

It is important to note that use of the term "exposure" implies that any means of expos-

ing the organism to stimuli will, on later testing, prove to have caused a "relatively permanent change in behavior" so far as this stimulus is concerned. Whereas the earlier investigations (for example, Gibson & Walk, 1956) were interpreted by many readers as implying such a simple state of affairs, subsequent investigations have shown that mere exposure may not be sufficient to cause later behavioral changes. For example, Gibson, Walk, and Tighe (1959) found that geometric forms painted on the walls of the living cages of rats apparently had no effects on later discrimination of those forms, whereas exposure to geometrical forms cut from sheet metal did have such effects, thus reproducing their original results. Gibson, Walk, and Tighe suggest that the three-dimensional characteristic of the metal cut-outs is an important factor in establishing the forms as stimuli which will be more readily discriminated in later training. It would therefore seem that "exposure" must imply something more than mere presence in the environment, and it is possible that some form of differential response to the stimuli is needed. However, the exposure procedures in these experiments in no way allow feeding or handling to be systematically paired with one stimulus, and the effects that are obtained are not limited to any special role played by the stimuli in later discrimination training. For example, the effect is seen as readily if an exposed stimulus becomes the negative stimulus in the two-choice discrimination situation as if it has been made the positive stimulus (Gibson et al., 1958). For such reasons, explaining away this phenomenon as due to secondary reinforcement does not seem reasonable.

It may seem strange that a process which seems to be so intimately involved with perception should be introduced by referring to experiments with rats, when perceiving itself is almost always studied with human subjects who can add their verbal reports to their nonverbal responses. In part, this is necessary because the animal experiments let us manipulate the conditions of prior experience which presumably influence the perceptual learning. Of course, most of us would not doubt that perceptual learning in humans does occur, if by that we mean that we learn what to perceive in certain situations. For example, when we are novices, we see and hear quite different things than are perceived by the master, but with accumulated, guided experience we begin to detect some of the features of the situation that formerly seemed to be just so much noise. After appropriate experiences, not only can we pick out details that previously had been hopelessly buried in the total flux, but we can also recognize patterns even when they are presented at lower intensities or for briefer intervals (change in recognition thresholds), and our effective reactions to the stimuli also become markedly altered. We experience these changes each time we enter some new situation, whether it is the learning of a new language or the techniques of wine tasting, or merely the accumulation of experience from hours of watching football on television. Usually the changes occur so slowly that it is difficult for us to remember that once we could not distinguish between what now seem to be the most gross differences; perhaps the skillful tutor is one who remembers better than the rest of us what some of those early difficulties were and can guide his pupil in the direction of detecting salient features of the stimulus situation. It is interesting to try to imagine what the infant or child must perceive in some of the situations which to us seem so well structured, and we know—from conflicts between members of different subcultures—how much the perceptions of the "same" situations depend upon the prior experiences of the perceivers.

However, if we wish to determine whether perceptual learning is distinct from the more familiar varieties of learning, we must eliminate the possibility that learning to perceive depends upon such processes. Suppose, for example, that the infant and child were differentially reinforced for responding to some aspects of the environment and not to others. Could we then account for the facts of exposure learning by reference to what we know about the role of reinforcement in operant behavior? In the world at large, the complexities of the situation make it impossible to discern the relative contributions of reinforcement to changes in the significance of stimuli, but in the laboratory, an approach to such problems is possible. Thus, the experimenter exposes rats (or some other convenient organism) to stimuli which presumably have no special significance, under conditions in which the reinforcement of differential responses to these

stimuli is unlikely, and he then tests to see whether mere exposure has changed the ways in which the organism reacts to those stimuli.

At the present time, the conditions that are sufficient for exposure learning to occur are not known, but it does seem fairly clear that the effects cannot be explained as due, in every case, to reinforcement of specific responses to the exposed stimuli during the exposure period. Nor does it seem likely that habituation of orienting responses to novel stimuli could account for the effects, for the change from the conditions under which the stimuli are exposed (living cages, for example) to those in which the effects of the exposure are tested (discrimination apparatus, for example) would certainly be sufficient to cause a reappearance of orienting responses. For the present, it seems that there is considerable reason to accept the exposure learning paradigm as one that produces a relatively permanent change which cannot easily be ascribed to other, more thoroughly studied procedures for modifying behavior. (See the discussion of the more perceptual problems involved in this question, in Chapter 13.)

Imprinting One of the most striking of all behavioral phenomena is that of imprinting. While the origins of this research can be traced back to Spalding (1873), the impetus for the present research on the topic seems to have stemmed from the work of Konrad Lorenz (1937). By now, most people are aware that the young of many species may "imprint" upon whatever conspicuous object is first exposed to them. The phenomenon has been studied primarily in species in which the young are capable of locomotion from the first day of life because locomotor responses are frequently used to evaluate the effects of the imprinting procedure. A typical experiment might expose chicks or ducklings to a flashing light or a moving object as soon as they are brought from the total darkness of the incubator into a lighted room. Later, most of the animals will follow this object and will emit "distress" calls in its absence and "contentment" calls in its presence. If faced with this object and a new one, they will ordinarily approach the familiar object and avoid the strange one. If presentation of the previously exposed object is contingent upon the emission of some more-or-less arbitrary response, the rate with which that response will be made will increase (Peterson, 1960; Hoffman et al., 1966). Similarly, if one side of a T maze leads to the imprinted stimulus, or to the alley in which imprinting took place, chicks will run to that side of the T maze (Campbell & Pickleman, 1961). In other words, not only is the imprinted object one which controls such behavior as following the object, but it also seems to control emotional responses, and it has demonstrable reinforcing properties. As a result, imprinting may determine both the initial and the adult social responses, and may influence the choice of adult sexual partners.

The favorite subjects for imprinting experiments have been ground-nesting birds because their young ordinarily are capable of walking within a few minutes of hatching and they can be incubated and hatched under nonsocial conditions. However, imprinting has also been claimed for mammals such as sheep, goat, buffalo, and zebra (Collias, 1956; Scott, 1958; Thorpe, 1963; Cairns, 1966). In such precocious animals, the assumption of imprinting is based on the responses of following an object other than the biological mother. For example, lambs reared by hand follow their human foster parents and ignore—and sometimes flee from—members of their own flocks. Continued exposure to flock living may reverse such early preferences (Thorpe, 1963, p. 404; Cairns & Johnson, 1965; Cairns, 1966).

More recently, there has been considerable interest in the possibility that newborn humans may show similar effects, with the infant becoming imprinted upon conspicuous stimuli in his prenatal and immediately postnatal environment. Of course, we cannot demand that the neonate follow a moving object to prove that he has been imprinted, but even

his quite limited response capabilities allow him to choose between objects and to maximize contact with certain stimuli. For example, when objects move about he can follow them with his eyes; he can become quiet, thus "following" in "auditory pursuit"; and he can "search" for objects within range of his mouth by twisting and turning his head. Using these responses, some researchers have concluded that imprinting (or something analogous) does occur in the neonate. Salk (1962) tested the hypothesis that infants become imprinted upon their mothers' heartbeats during the latter portion of the prenatal period by presenting a "lub-dub," imitation heartbeat sound to 102 infants during the first four days of life, and compared their weight gains with a control group not exposed to the sound. The rationale for measuring weight gain as an index of imprinting involved the following assumptions: If imprinting occurs, the presence of the imprinted stimulus produces emotional tranquility, while its absence produces fearfulness and anxiety; an emotionally upset or anxious infant should eat less and gain weight less rapidly than a nonanxious infant. It was also assumed that the lub-dub sound presented to half the infants was a reasonable replica of the stimulation that each fetus received through the tissues and fluids surrounding him before birth. The group that was exposed to the lub-dub sound did indeed gain significantly more weight than the controls, thus supporting the hypothesis that imprinting *in utero* had occurred. Ideally, there would have been a control group exposed to auditory signals not like the supposed imprinted stimulus; it was not possible to include that condition in the first experiment, but Salk (1966) did compare lub-dub with other signals in a subsequent study. In this case, toddlers (16 to 37 months old) were assigned to groups, each of which was exposed to a different sound at bed time. One group heard the 72 lub-dubs a minute of the imitation heartbeat, another heard lullabies, and a third group heard 72 single "dubs" per minute. The dependent variable was the time taken to fall asleep, again assuming that decreased fearfulness or anxiety should result from presentation of an imprinted stimulus, and that the stimulus should thus encourage relaxation and sleeping. The results supported the hypothesis: The experimental group required (on the average) only half the time needed by the others to fall asleep.

One of the most general ways of describing the effects of initial exposure to such stimuli is that the effective range of stimuli for a given response is subsequently narrowed (see Hinde, 1970, p. 509ff.). The chick who is exposed to a flashing orange light when he first emerges from the egg will follow that light (and similar ones; Cofoid & Honig, 1961). By thus promoting an attachment to this stimulus, the early experience has largely eliminated the possibility that other stimuli will be followed. From a variety of observations, it is concluded that there is a "sensitive" period during which such attachments are most readily made, and some investigators have suggested that such phenomena may occur in humans as well as in other species. For example, Gunther (1955) provides evidence that the first few days in the infant's life are the sensitive period for nursing and that if the responses of suckling are to become firmly attached to the stimuli of breast or bottle, the exposure must occur during this period.

The earlier reports of imprinting by Lorenz (for example, in 1937) emphasized the following features of the phenomenon. First, it was said to be a process which could occur only during a very limited period during which the organism was in some critical stage of development, and that if an object were exposed at some time outside this critical period, imprinting would not occur. Second, the effects of imprinting were said to be irreversible. Third, it was said that the process was a sudden and an all-or-none phenomenon.

It now is known that all three of these statements must be modified. The "critical" period has been shown to be a rather broad one, and as a result, most writers now prefer the term "sensitive period." Although there
Figure 14.5. Imprinting as a function of age at exposure to imprinting stimulus. Mallard ducklings were kept in isolation from hatching until placed in the imprinting apparatus, where they were exposed to a model of a *male* mallard. The model moved slowly around the circular enclosure, emitting a recorded "gock, gock" sound. Ducklings were removed from the enclosure after they had followed the model 150–200 ft in 10 min. Between imprinting and testing, they were kept in isolation. Tests consisted of releasing the duckling midway between the male model and a female model. In order, each duckling was given the following tests: (1) Both models silent, both stationary; (2) Both calling, both stationary; (3) Female calling, male silent, both stationary; (4) Female calling and moving, male silent and stationary. These tests are thought to represent increasing likelihood of a non-imprinted duckling approaching the female model. The percent of all ducklings earning a perfect male-following score (thus indicating strong degrees of imprinting) increased as age at time of imprinting increased, reaching a maximum at 13–16 hours, and then falling. The decline probably reflects increasing fearfulness of the model when the first exposure to it is delayed until 20 or more hours after hatching, for by then the duckling has already become familiar with the appearance of his environment. Moltz and Stettner (1961) prevented such familiarity by placing light-diffusing hoods on their ducklings; for these animals, the "sensitive period" for imprinting was extended to 48 hours or more, thus supporting their hypothesis that the sensitive period is not completely determined by maturational processes, but at least partially influenced by prior sensory experiences. (Hess, 1959.)

is a period of peak effectiveness in most species in which imprinting occurs, the procedures are effective over a rather broad period. For example, in the domestic varieties of chick, and in many ducklings, the first exposure may be given during any of the first seven or more days of life. Of course, it is essential that no other conspicuous stimuli be presented to the animals before their exposure to the stimulus to which they are to be imprinted. The hatchlings may be left in the dark for two, or possibly three days, for they will survive quite nicely for this period on their remaining yolk sacs; if longer periods are needed, they may be isolated and placed in homogeneous environments, or they may be fitted with visual occluders. Such isolation is necessary to prevent imprinting on the other chicks. Usually the emphasis is on the control of visual stimuli (to which these animals seem to be most sensitive), but it can also be shown that they will imprint upon auditory stimuli (Bateson, 1966, pp. 187–188); hence "isolation" should be acoustic as well as visual.

If separate groups of animals are removed from isolation and exposed to the imprinting stimuli at different ages, the typical result is a nonmonotonic relationship, with a period during which peak effectiveness of the imprinting procedure is attained, and with relatively less effectiveness if the exposure occurs earlier or later (Figure 14.5). This relation between age and the effectiveness of imprinting usually has been interpreted as an interaction of two factors. The initial increase in effectiveness is thought to reflect nothing more than the increasing maturity and perceptual-motor ability of the organism. The decline in effectiveness after a few days has been variously attributed to a decline in an innate tendency to follow moving objects (Lorenz, 1937); or to an inhibition of following caused by incompatible responses, such as fear reactions, which are more readily elicited as age increases (Hinde, Thorpe, & Vince, 1956; Hess, 1959); or to an increasing awareness of what characterizes the normal environment, with increasing likelihood that non-normal (that is,

novel) objects will elicit fear responses which inhibit following and elicit withdrawal (Moltz, 1963; Bateson, 1964; Sluckin, 1965). Indeed, this matter of learning what is the normal environment, and becoming "attached" to it, has been suggested as one of the key features of imprinting (Thorpe, 1963, pp. 416–418).

It had once been thought that all imprinting was much more permanent than other modifications of behavior by experience, but although animals may continue to follow the objects on which they have been imprinted for weeks or even months, in other cases, the effects are found to last for much shorter periods. In the natural situation, the young of most precocial species follow the mother closely for the first few days or weeks, but gradually they widen the area over which they roam. Eventually, of course, they must cease to follow the mother, else adult behavior, such as pairing for mating purposes, could never occur. Furthermore, when the young female becomes sexually mature, she responds appropriately (which in some cases includes following . . .) to a male and not an organism that looks exactly like her mother. These facts of life remind us that imprinting is not necessarily permanent nor all-pervasive; that some of the stimulus dimensions to which imprinting occurs may be quite broad ones (such as general shape of body or head) which may then serve important roles in recognition of one's own kind; and that in some other situations, imprinting may occur to highly specific stimuli (body odors, for example), which allow offspring to identify their mothers—and vice versa (Hersher, Richmond, & Moore, 1963).

In less natural situations, lifelong effects of early exposure have been noted. For example, Lorenz (quoted in Thorpe, 1963, p. 407) exposed some newly hatched budgerigars to himself and one of his colleagues. The birds then were isolated from humans for two years, during which time they bred and reared young. However, after this period, when they were first reexposed to Dr. Lorenz, they immediately courted him and neglected their own kind. Perhaps such rather permanent effects of initial experiences might also be seen in nature, save for the fact that there is continual stimulation from changing situations and reinforcement of variations in responding. Such changes are less likely to occur among caged birds (such as Lorenz' budgerigars) because their keepers maintain rather constant conditions and minimize the opportunities for the reinforcement of new responses.

Perhaps it is worth mentioning at this point that other behavior modifications may also be so long lasting as to appear permanent and irreversible. Food preferences, attitudes and prejudices, and language skills are familiar examples of acquired behaviors which change but little over the years, even when the conditions of living are such that some of the responses are emitted but rarely and thus but rarely reinforced. Even more impressive are the laboratory studies which show essentially no effects of time on retention even though it is certain that no possibility for further practice had been offered during the retention interval. A well-known example is the perfect retention of a visual pattern discrimination by a pigeon after seven years of "retirement" (Skinner, 1960). No one would claim that such perfect and long-lasting discriminative responding would be irreversible. Instead, they probably would suggest that the errorless retention was attributable to the lack of opportunity for incompatible or interfering responses during the retention interval. The same logic could be applied to Lorenz' budgerigars: by isolating them from humans during the two-year interval, the birds were protected from the interfering responses which otherwise would have occurred, and the perfect retention of their approaches to humans might just as reasonably be attributed to this isolation from interference as to some special characteristics of the attachment to the imprinted object.

The apparent irreversibility of imprinting suggested to Lorenz that this was a phenomenon quite distinct from the usual forms of learning. When Lorenz presented himself to newly hatched goslings, it was the creeping, honking Lorenz that the goslings followed—and they continued to follow him when they became juveniles and adults. However, even though Lorenz' geese failed to form appropriate social attachments to others of their kind, showed distress when Lorenz disappeared, and courted him while ignoring their own species, other observations suggest that early imprinting does not necessarily make later attachments to different objects impossible. In commercial breeding establishments, for example, domestic fowl are frequently used to hatch out gamebird eggs (such as partridge or pheasant). Although the hatchlings follow the foster mother closely and

show distress at her absence, they seem to have no difficulty in later mating with their own kind. Such observations suggest that the apparent "permanence" and "irreversibility" of attachments shown by some animals for their foster parents are not inevitable, and such preferences as are shown may be overridden by later experiences.

> Relatively permanent social and sexual attachments are not necessarily caused by short exposures to an object during a particular sensitive period. For example, the studies of developing affectional relations in rhesus monkeys (Harlow, 1958, 1959, 1961; Harlow & Harlow, 1962) indicate that the ties between infant and mother (or surrogate mother) are not formed instantly and that they are significantly modified by day-to-day experiences. The infant reared with a soft and warm substitute mother clings to her, as if the sheer tactual stimulation is of itself sufficient reinforcement to create a strong attachment. In the presence of novel stimuli, the infant runs to the figure in the same way that infants reared with their own mothers flee to them when frightened, and he continues to do so long after the nursing function of the mother substitute has ceased. In another context, those young monkeys denied the opportunity for the usual interactions with behaving mothers and the rough-and-tumble experiences of youthful play are later found to be inept in or incapable of mating and mothering. All this sounds like "irreversibility," but although the limits of change have not been thoroughly explored, it is clear that the infant monkeys can adopt a new mother surrogate and develop what seem to be "normal" relations with her as late as the eighth month, as compared with the usual attachment which occurs in the first days of life (Harlow, 1958). Here, then, is the development of a set of filial and affectional relations which seem at least as "permanent" and "irreversible" as any of the adequately documented cases of imprinting, but the relations are developed rather slowly, the sensitive "period" is apparently quite broad and rather flexible, and, given the opportunity, subsequent experiences can modify at least some of the affectional relations and object choices.

The third of the three characteristics of imprinting was said to be the sudden, all-or-none nature of the process. As usually observed in the field or barnyard, imprinting does seem well described by such terms: The chick nestles under the hen, follows her closely if she moves, emits "distress" or "contentment" calls depending on her absence or presence, and seems to do all these things with great proficiency from the very first day. However, systematic study reveals that there are some fairly large individual differences in the behaviors of chicks. The latency to the first act of following, the proportion of opportunities on which following occurs, and the closeness with which the chicks follow all show considerable variation between individuals (Jaynes, 1956; Salzen & Sluckin, 1959), suggesting that imprinting may occur in varying degrees among chicks given the same initial exposures. Such differences are not merely the result of general weakness or the stupidity of the animals which show little or no evidence of imprinting: Fischer (1966) compared chicks that gave strong evidence of imprinting with those that gave no such evidence at all, and found the two groups indistinguishable on a variety of discrimination problems.

The apparently simple question of whether or not the effects of imprinting occur in an all-or-none manner, going from absence to full presence at a single exposure, is really not answerable, since the dependent variables that are employed are not pure measures of degree of imprinting. For example, if the following behavior of birds is observed over the first few days, those that follow at all usually follow more vigorously and dependably on successive "practice" days (for example, Jaynes, 1957; Bateson, 1964a); but this might indicate nothing more than an increased maturity and ability to follow, and the "attachment" underlying the overt behavior indeed might exist only in two stages: zero and full strength. As measured, indices of following behavior, signs of recognition (as inferred from vocalizations or failure to avoid objects), and choice behavior in discrimination situations all increase as the number of exposures to the model increase. (However, these functional relations are distorted, if they are plotted over several days, by the declines that

occur as a function of age.) Thus, although it is frequently the case that the effects of the imprinting procedure occur over a relatively short time period, the degree to which the "attachment to the model" is formed probably is a function of the amount of exposure, the opportunity for approach responses, and so on.[19]

Before concluding that imprinting is a unique process, we should consider the possibility that it might be deduced from one of the other means of producing behavioral modifications. For example, might all the phenomena of imprinting be based on classically conditioned responses? To defend such an argument, we would first have to postulate certain unconditioned (but not necessarily species-specific) responses. Suppose, for example, that the members of some (or all) species orient toward and approach (within the limits of their capabilities) whatever is the first conspicuous stimulus to which they are exposed. This might not be too far-fetched an assumption, for orienting and investigatory responses are characteristics of most forms of animal life. Because some of the characteristics of this stimulus object would inevitably be more conspicuous than others, these might become the conditioned stimuli for the approach responses which were initially elicited by the object just because it was the first one exposed to the organism. Thus, on later occasions, approach might be elicited by the CSs even though the unconditioned reactions on which the process originally was based no longer exist.

The hypothesis that an unconditioned reflex might decline with age is not unreasonable: The Babinski and the palmar grasping reflexes are well-known examples of just such changes. Neither should we be greatly troubled by the assumption that some characteristics of an object or situation may serve as the US while other features of the same object become CSs. An everyday example of this situation is the sight of food, which becomes the conditioned stimulus for salivation because it has been paired with the US of food in the mouth. Nor should we find it too difficult to accept (tentatively) the very vague description of the US as "the first conspicuous stimulus to which the organism is exposed," for there are many such imprecise descriptions of unconditioned stimuli which have been found fairly useful. Well-known examples are the "novel" stimuli that elicit orienting reflexes, or "sudden" or "intense" stimuli that elicit startle or fear, or the "strange" and "unusual" objects that evoke emotional upsets (see Hebb, 1946; Melzack, 1952).

The most obvious difficulty faced by any attempt to force all instances of imprinting into a classical conditioning mold is that such an interpretation would require that whatever responses occurred during the first presentations of the conspicuous stimulus should be the ones conditioned to the stimulus and, on subsequent occasions, elicited by it. So, if we present the stimulus but prevent any approach behavior, subsequent presentations should not yield approach. Such experiments have been done (for example, by Moltz, Rosenblum, & Stettner, 1960); the general result has been that *equally strong following* occurs on later tests whether the animals have been exposed to the model under "normal" conditions, where they can approach and follow, or under restricted conditions, where they are held in restraining chambers.

Attempts to explain imprinting by reference to well-known principles of operant behavior have not been any more successful. To fit the model, it would be necessary to demonstrate that (1) the nature of the response during the initial exposure is relatively unimportant, so that almost any one of a large number of responses might be substituted (just as treading on a pedal may be substituted for pecking a key, if convenience is served by such selection), and (2) the pres-

[19] The common indices of imprinting are: approach toward the imprinting stimulus; decrements in emotional upset and/or increments in contentment, as evidenced by vocalizations, food ingestion, nestling, etc.; positive reinforcing effects of the imprinting stimulus; and choice of the imprinting stimulus over other stimuli. The latter test seems to be the least ambiguous.

entations of the conspicuous object increase the probability that the arbitrarily selected response will occur and that subsequent withholding of the stimulus produces typical extinction phenomena.

On the first point, the evidence is unequivocal: The nature of the response is not immaterial; it is what is usually called an *elicited* response rather than an emitted one, for its original occurrence is under the control of the conspicuous stimulus. Thus, we may conclude that the typical "filial" behavior, of which following responses are so conspicuous a part, is not an operant that is reinforced by presentation of the stimuli from mother or model.

This does not mean that such conspicuous stimuli cannot reinforce other responses, or that they cannot reinforce and further strengthen approach and following behavior. Imprinted stimuli may be rather effective reinforcers, allowing an arbitrary response (such as pecking a key) to be strengthened if brief presentations of the stimulus are contingent upon emission of such responses (see, for example, Peterson, 1960; Hoffman et al., 1966). However, stimuli need not be "imprinted" to have reinforcing properties, for at least some such stimuli are quite effective reinforcers in the absence of any prior exposure. For example, Bateson and Reese (1968) imprinted chicks and ducklings on a rotating light and then made presentations of the light contingent upon depression of one of the pedals in a chamber containing two pedals. They demonstrated acquisition, extinction, and reconditioning of this pedal response by the previously imprinted birds. However, they also showed as great—or greater—a reinforcing effect from presentations of the light to birds that had been kept in total darkness during the time the others were being imprinted. We may conclude that the reinforcing effects of such stimuli do not necessarily depend upon prior imprinting and, in some cases, the same stimuli that are effective in imprinting may also be effective reinforcers in operant situations in the absence of prior imprinting. Such reinforcing effects of "stimulus change" have been demonstrated in many different situations with more mature organisms as well as with very young ones (see p. 673), and although they may not account for all the rich variety of behavior encompassed by the term "imprinting," they certainly complicate the situation, for in the very first presentations of the mother or model, whatever operants occur (approach, for example) must immediately be rendered more likely to occur again by the reinforcing properties of many such stimuli.

Thorpe (1963) has suggested that imprinting and exposure learning have much in common and may be basically similar, and Sluckin (1965) seems to agree. However, we must also take into account the fact that, in imprinting situations, the conspicuous stimuli elicit approach when first presented, and this is not deducible from the facts of exposure learning. To bridge this gap, it is sometimes assumed that the animal will approach any conspicuous object during the "sensitive period" of life; that increasing fearfulness of objects not previously encountered develops during this period, bringing it to an end; and that exposure learning plays a role by establishing which stimuli are familiar and which strange (see Bateson, 1964b; and Hinde, 1966, pp. 368–369). Thus, although the basic paradigms for exposure learning and imprinting are the same (expose stimulus, test for recognition), the overt approach reactions and the emotional attachments of the imprinting situation are not typically observed in exposure learning situations. For the present, it seems that imprinting might profitably be considered as a complex situation involving several unconditioned (and sometimes species-specific) reactions, some of which may determine the reinforcing properties of environmental stimuli, and some of which may also determine the nature and strength of emotional reactions to such stimuli. There does not seem to be any special advantage in assuming, at this time, that imprinting is some special form of learning process, or that it involves principles

which are unknown in other contexts. (For valuable reviews and analyses of imprinting, see Moltz, 1963; Thorpe, 1963; Klopfer, 1965; Sluckin, 1965; Bateson, 1966; Hinde, 1970.)

Habituation

In the most general terms, a response may occur at a constant rate, or it may increase or decrease in rate. Reinforcement is one of the major determinants of rate increases and extinction is an important cause of rate decreases, but there are other ways of producing the same effects. For example, motivational changes (such as deprivation and satiation) may cause either increases or decreases in response rates, and inherent (such as circadian) rhythms may do the same. Sensory adaptation (for example, p. 283) is a frequent cause of decrements in response rate, as is simple fatigue. Habituation also causes decrements in responding, but although adaptation and fatigue (and many of the rhythms) can be analyzed without invoking so complicated a process as learning, habituation appears to be very much involved with such problems. Indeed, it is possible that habituation is one of the most rudimentary forms of. learning, and thus of central importance to an understanding of how experiences are coded, stored, and retrieved.

Habituation and the orienting reaction Most frequently, the term "habituation" refers to the waning of orienting (investigatory) responses after repeated presentations of a "neutral" stimulus. These orienting reactions include: "targeting" responses (like turning toward the source of a sound, or sniffing) which increase the probability of receiving further stimulation from the CS; autonomic responses of the type usually mediated by the sympathetic portion of the autonomic nervous system; and desynchronization of the rhythms of the electroencephalogram (Konorski, 1967). During the first tests of a stimulus, the orienting responses would be seen in their full form; with successive presentations, decrements in the magnitudes of all three aspects of the reaction usually occur.

The orienting reaction is, of course, an unconditioned one, and the stimulus which elicits it is an unconditioned stimulus, but because the reaction wanes so readily, such US-UR combinations cannot be made the basis for ordinary classical conditioning. However, it is possible that such relations might underlie "sensory preconditioning" (see p. 564). For example, if a light and a tone are paired, the light might acquire some control over the orienting reactions normally elicited by the tone. Such reactions (pricking up the ears, for example) would also occur in later conditioning sessions, when the tone is paired with a durable US, such as food. If the CS for the salivary CR is not just the tone, but also the stimuli caused by orienting reactions to the tone, it is possible that the light could cause some salivation, inasmuch as the light causes some of the same orienting reactions. Such effects, based upon mediation via shared portions of the orienting reaction, might be expected to be weak and transient, since the orienting reaction itself wanes so readily. Sensory preconditioning typically is such an evanescent phenomenon.

Note that the operations involved in habituation and extinction are exactly the same: repeated (or continuous) presentation of a single stimulus. In extinction, of course, the stimulus previously has been established as a CS, and the response that is waning is the CR; in habituation, the stimulus has not been paired with a US, and the response that is waning is the UR to it (that is, the orienting reaction).

Other response decrements In recent years, "habituation" has been applied to a much wider range of phenomena than just those associated with orienting reactions, so that it now is quite commonly applied to all response decrements (1) associated with repetitious presentations of a stimulus, where (2) the stimulus is not a CS, and (3) where sensory adaptation, fatigue, satiation, and inherent rhythms may be discounted as causal factors. Adaptation and fatigue may sometimes be ruled out if the response *reappears* when the stimulus is altered by *reducing* its intensity, for an adapted or fatigued sensory system should not be expected to react to the first *decrease* in stimulation. Varying the stimulus interval can be used in the same way.

Satiation effects should be relatively slow to disappear, whereas recovery from habituation is essentially instantaneous, thus allowing these effects to be distinguished. Rhythmic changes in activity usually occur over sufficiently long intervals and swing both towards increases and decreases in activity, so that there is rarely any difficulty in distinguishing these from habituation.

Contemporary usage applies "habituation" to decrements in all types of responses, from adjustments to environmental temperatures or elimination of seasickness (Glaser, 1966), to the waning of reactions in isolated neural preparations (see Horn, 1967). The term obviously fills a vacuum that had existed in our technical vocabulary, but there is the possibility that its usefulness will be diluted by even wider applications.

Of course, there are some unconditioned responses which do not show habituation (and these make the best unconditioned stimuli), but even in the most persistent cases, some change in the response pattern usually can be detected. For example, a moderately intense electrical shock will usually elicit vocalizations, withdrawal, or struggling, and increased heart rate, blood pressure, and other signs of autonomic upset. If it is repeatedly presented, the shock may gradually cease to elicit the vocalizations and struggling, suggesting that even with so salient a stimulus there is likely to be at least some degree of decrement for every facet of the elicited behavior.

The time course of habituation The general pattern of changes in responding during habituation is reasonably described by the familiar negatively accelerated curve. That is, the reaction to the stimulus decreases with successive presentations, but the absolute amount of the decrease per stimulation declines as the number of stimulations increases. Because this functional relation also is characteristically found in studies of sensory adaptation, fatigue, and extinction, and because the operations for habituation, adaptation, fatigue, and extinction all involve the successive (or continuous) presentation of stimuli, it is sometimes difficult to decide which label is the appropriate one for a given experiment.

These problems are illustrated in the investigations of the mobbing responses of chaffinches (*Fringilla coelebs*) by Hinde (1954a, b; 1961). "Mobbing" refers to the behavior shown by many species of bird in the presence of a predator, and usually includes a characteristic call as well as the motor behavior of alternating approach and withdrawal. The "chink" call emitted during mobbing by chaffinches (and at other times when the bird is disturbed) occurs once or twice a second when a novel stimulus is introduced. In the wild, when chaffinches discover a predator, they chink loudly.[20] If the predator moves out of range, the chinking dies down; but even when an immobile predator is found in the immediate vicinity, waning of the chink calls eventually occurs. For example, an owl may remain sleepily in place while being mobbed, but even though the owl has not left the area, the chinking may subside.

Considering the survival value of mobbing (that is, alerting others to the potentially dangerous object), it is somewhat surprising that the behavior shows any waning. These field observations have been confirmed and extended by controlled laboratory experiments. In one such experiment, each chaffinch was in turn exposed to an owl placed just outside its aviary. Under these conditions, the behavior appears to be much the same as that seen in the field: There is an initial retreat to a distant perch, and during the first minute or two the rate of chinking increases to a maximum; it then declines over the next half hour or so. Moreover, if the procedure is repeated day after day, a sys-

[20] Calls when a nonflying predator is encountered tend to be abrupt and therefore easily localized; calls when a flying predator is seen are usually more drawn out, with gradual onsets, and therefore difficult to localize. For communication purposes, such calls probably are equally efficient, and they have the advantage of letting others know where a nonflying predator has been located while not giving away the location of the callers to the flying predator (Marler & Hamilton, 1966).
Figure 14.6. Decline in "chink" calls emitted by chaffinches on successive daily tests with a live owl. Each chaffinch was exposed to the owl for 20 min a day. The number of calls emitted by each bird on each day was expressed as a percentage of the number of calls he made on his first day of exposure; the mean of these percentages is plotted in this figure. (After Hinde, 1954b.)

tematic decrement takes place in the amount of daily chinking (Figure 14.6).

Consider first the waning of the response during a single session: How are we to distinguish between the effects of (1) fatigue of the mechanism involved in chinking; (2) sensory adaptation to the novel stimulus (the owl); (3) extinction of a previously conditioned response; or (4) habituation? Fatigue seems an unlikely explanation, since introduction of a new stimulus (for example, a stuffed dog) produces an immediate recovery in chinking. Sensory adaptation seems unlikely to occur when stimulus conditions are constantly varying, as they do in these experiments. Extinction presumes prior conditioning, but it is unlikely that mobbing behavior is a conditioned response, since it also occurs when stuffed figures are shown to birds that have been reared in the laboratory where they have seen no other animals and could not have acquired either the fear of predators or the specific responses of reacting to them. Furthermore, when the day-to-day decrements (Figure 14.6) are considered, fatigue and sensory adaptation seem even less likely explanations. We are left, therefore with the conclusion that the waning of the mobbing behavior cannot be satisfactorily explained by any one of these other well-known phenomena, and that the use of yet another label ("habituation") is warranted.

It would be dangerous, however, to conclude that there is a single behavioral or physiological process underlying all the decrements in mobbing, for within the overall systematic decrement can be detected a variety of local changes. In the mobbing behavior of chaffinches, for example, Hinde (1954b) has identified both positive and negative effects of the presentation of predators. The waning, for example, shows short-term effects from which there is considerable recovery if the stimulus object is removed for just a few minutes, and it also shows long-term effects which are relatively permanent. Within the short-term effects, there appears to be a warming-up effect, as chink calls increase in frequency during the first minute or two before beginning the overall decrement. Within the long-term effects, there is a *decrease* in the latency to the first response on successive daily sessions, even while the total number of chinks per session decreases.

Similar complexities exist when decrements in responses are studied in newborn humans, where the effects of prior experience may be assumed to be minimal. For example, in studying the reactions of neonates to a combination of odors, Engen and Lipsitt (1965) found a short-term decrement which was essentially complete in ten presentations of the odorants, with each presentation lasting 10 sec, and one trial being given each minute. That this was not sensory adaptation was shown by the recovery to the preexposure level of the response to one of the two odors in the compound when it was presented alone, immediately after the series of ten exposures. Instead, it seems that the change from stimulation with the compound to stimulation with just one of the elements

of that compound introduced a degree of novelty into the situation which might account for the "dishabituation." This emphasis on the role of novel stimulation has been characteristic of many recent experiments on habituation, and it seems especially appropriate when the habituating and the dishabituating stimuli differ only in pattern or sequence. For example, Bartoshuk (1962a, b) examined the response decrement shown by infants to repetitive presentations of auditory stimuli and found that the response recovered when the pattern of the stimulus was changed. For example, if a rising tone had been used as a stimulus, successive presentations produced a decrement, but the first change of the tone to one which fell from high to low pitch caused a recovery in the response. Such decrements following repeated stimulation can be demonstrated after a 24-hour interval, indicating that long-term effects as well as the short-term ones exist even for human neonates (Keen, Chase, & Graham, 1965).

Habituation and neuronal models of learning These complexities are emphasized here because it has sometimes been assumed that the type of waning of responses called "habituation" is a simple (and a single) process. As we have seen, it sometimes is possible to detect several different behavioral changes within overall habituation effects. It therefore is as important to control conditions of stimulation and past experience in habituation experiments as in any other behavioral investigation (see Hinde, in press). Still, because this decremental change seems to represent a *relatively* simple effect of experience, habituation has been receiving increasing attention in recent years. This has been especially true of researchers seeking the physiological and anatomical correlates of learning, for response decrements of the type called "habituation" can be demonstrated in organisms whose nervous systems are relatively simple and hence relatively better understood than those of organisms usually used in studies of learning and retention. For example, the sea slug, *Aplysia*, has an abdominal ganglion of relatively few cells, some of which are very large, which simplifies considerably the stimulation and recording of electrical and neurohumoral changes. Some of these giant cells have been found to change their excitatory postsynaptic potentials to a "test" stimulus applied to one of its input nerves if that stimulus previously has been paired (in the manner of classical conditioning) with a "priming" stimulus delivered to another of its input nerves. Appropriate controls have shown that this change does not occur when the two stimuli are presented in a nonpaired manner (Kandel & Tauc, 1965). Response decrements to repeated stimuli and recovery under novel stimulation conditions have also been observed, suggesting that the ganglia show "habituation" (Kehoe & Bruner, 1966). The motor cells controlling spontaneous or reflex withdrawal reactions of the siphon have also been identified, so that modifications of gross behavior may now be studied (Kupfermann & Kandel, 1969).

Such observations are obviously relevant to any attempt to construct a neuronal model for learning. Pavlov (1927) concluded that habituation of the investigatory reflex was a reflection of changes in the cerebral cortex, and there is now very good evidence that changes of this type do occur. For example, the arousal pattern in electroencephalograms shows a systematic waning as a stimulus is repeatedly given (see, for example, Knott & Henry, 1941; Sharpless & Jasper, 1956; Sokolov, 1960). However, what seems to be a similar type of waning also occurs at lower levels in the central nervous system (see, for example, Hernández-Peón & Brust-Carmona, 1961). Furthermore, similar decrements also occur in the hind limb reactions of spinal animals (Prosser & Hunter, 1936; Thompson & Spencer, 1966; Spencer, Thompson & Neilson, 1966), where the cortex cannot influence the waning.[21] In addition, there are numerous studies demonstrating habituation, dishabituation, and maintenance of the decrements over time in lower organisms possessing no tissues analogous to the cerebral cortices of higher vertebrates (see, for example, Humphrey, 1933; and the survey in Thorpe, 1963, especially Chapter 10). Finally, we may mention the experiments of the type mentioned above, showing these same effects in individual cells or groups of cells (see, for example, Kehoe & Bruner, 1966; Horn & Fraser Rowell, 1968).

For these and similar reasons, Horn (1967) has suggested that a "low-level" mechanism (or mechanisms) might mediate habituation in many cases. He postulates a self-generated depression

[21] In a spinal preparation, the spinal cord is transected, thus preventing impulses resulting from the experimental treatment from reaching the brain. Habituation of hind limb reactions therefore could not be attributed to the action of the cerebral cortex when a spinal preparation is employed.

of sensitivity resulting from repetitive stimulation of neurons, such that responses at these more-or-less local levels would lessen with stimulation while sensitivity to altered stimulation would be maintained. Sensitivity is assumed to recover after an interval of no stimulation. Such changes in sensitivity might result from a progressive reduction in the available supply of transmitter substance in the synaptic terminals of the stimulated system (Bruner & Tauc, 1966), with different "circuits" being excited by different stimuli. This line of thought likens habituation to sensory adaptation but places the mechanism outside (and more central than) the immediate receptor system.

All the models of habituation involve one common assumption: Somewhere there is a "comparison" made between stimuli that have been presented in the immediate past and the stimulus just now arriving. In this sense, habituation might be thought of as involving a form of perception (Konorski, 1967). The distinction drawn between habituation and other decremental processes (such as sensory adaptation or fatigue) is that in habituation, the sensitivity of receptors and effectors is thought to be unaltered. The changes are assumed to be occurring in cells more central than these.

Some writers have also emphasized the duration of habituation in contrasting it with adaptation or fatigue. For example, Thorpe (1963) has observed that ". . . the long-maintained waning of response as a result of a stimulation must be a kind of learning, and we assume that it is correlated with a change in the central nervous system and not merely with one in the sense organ" (p. 62). This, of course, is frequently the criterion used to decide whether a response decrement is a form of learning: Does it persist, showing effects on a later retest or transfer test? If it does, it is assumed that we cannot attribute it to more peripheral—and better understood—factors. This seems to be true of habituation, and, in this and in other respects, it seems to be consistent with our usual usage of "learning" to apply the term to habituation.

Verbal learning The earliest systematic studies of learning processes were those of Ebbinghaus (1850-1909). Working by himself, he tested his acquisition and retention of connected verbal materials (such as poems) and lists of discrete items. For the latter, he used both words and relatively meaningless "nonsense syllables," which he invented in an attempt to minimize associations between items. To conduct his experiments, he devised procedures for controlling practice and measuring retention. The results of his early experiments were reported in a monograph (Ebbinghaus, 1885) which inspired many others to undertake research in the experimental psychology of learning and forgetting. Research in this area was therefore well under way before Pavlov began his studies of "psychic reflexes" and while Thorndike was still a mere schoolboy.

In light of the historical priority of the use of verbal materials in the experimental psychology of learning, and in light of the fact that this interest area is one of the largest in experimental psychology, it may seem strange that this topic is relegated to last place in a survey of basic approaches to the study of learning. There are two reasons for this: (1) "verbal learning" is a description of the *materials* that are used in experiments, and not of the methods employed; and (2) there are now so many specialized techniques for the presentation and control of these materials, and for the regulation of practice conditions, that no brief survey could begin to mention their most salient features. (The concluding three chapters of this book deal almost exclusively with problems related to verbal materials, as well as the basic paradigms employed in such experiments.)

There are, however, a few rather general statements about verbal learning that may help place this topic in perspective. In the first place, verbal learning frequently is studied with exactly the same techniques that are used for the investigation of other forms of operant behavior. However, since verbal materials may be manipulated covertly, additional problems of control are raised. Under the conditions of most experiments, a subject is free to repeat the materials to himself dur-

ing, between, and after trials; thus, he may engage in periods of practice or rehearsal that are not directly under the control of the experimenter. Where such uncontrolled manipulation of materials is to be minimized, experimenters sometimes introduce a conflicting task, such as mental arithmetic or color naming (see pp. 1028, 1035). This, of course, greatly increases the number of problems the experimenter must deal with, as compared, for example, with the between-trials vigilance needed by the Pavlovian researcher, who can maintain secure control over the occurrence of the stimuli—and thus exercise control over the responses—in his experiments.

Verbal materials frequently are treated in the same manner as nonverbal operants, with the experimenter presenting or withholding reinforcements to manipulate the behavior. In such experiments, the experimenter may say "good" or "um-hum" following certain responses, or he may advance a counter that indicates the number of points earned by the subject. In many other experiments, however, no special event is programmed to follow correct responses, it being assumed that recognition and confirmation are sufficiently potent factors to insure that positive practice effects will occur. This is a second characteristic of many verbal-learning experiments, and one which distinguishes them from most other experiments in learning: The experimenter may decide not to program any special reinforcers, and he may even do his best to eliminate any rehearsal and/or subsequent recognition of the materials previously presented.

The various procedures developed for the study of verbal learning share only one common characteristic: They all use materials that can be verbalized. Although this is a trivial generalization, it nevertheless deserves mention, for it sometimes is overlooked in comparisons of experimental results. For example, every time human subjects are used in an experiment, it is reasonable to assume that some subjects will verbalize materials if it is possible to do so; they will convert the problem into a verbal-learning experiment regardless of the desires of the experimenter. If a finger maze problem is presented, the majority of college students will immediately attack it as a problem to be coded into verbal form: Some will grope their way through the maze, trying to remember the sequence of choice-point turns in terms of patterns of "left" and "right"; others may discover in the earliest moments that they need only code responses as left or right, and so they need discover and memorize only the numbers of the choice points where they must, for example, go to the left. If the maze has, let us say, eleven choice points, a student following the first scheme would have to discover and memorize an eleven-item list made up of the responses "left" and "right"—a task offering many opportunities for within-list interference. The other student has only to discover and remember the numbers (for example, "1, 2, 4, 6, 7, 9") which will serve to identify the ordinal positions of choice points at which the correct response is "turn-left." Not only has this student a shorter list to remember, but there is much less chance that he will be confused by intra-list interference, for each item in his list is a different digit.

Still other techniques for coding the maze in verbal terms may turn up in the course of the experiment, but it is almost certain that the error or time scores of students who use any such verbal procedures will not be comparable with those of students who attempt to learn the finger maze in nonverbal terms (as, by forming a mental picture of the route or gaining a kinesthetic image of it). For example, if we plot the number of errors made at each choice point in the maze during all the trials needed to master it, those subjects who try to discover and memorize the serial list of left-right responses will ordinarily produce the familiar *serial position curve* (see p. 1015). They will have made relatively few errors at the first and second choice points, somewhat more at the next points, and relatively few again at the last choice points, making the greatest number of errors just past the midpoint of the maze. In contrast, subjects who go through the maze discovering which number is, for example, a "left" usually master the task in just a few trials and show no discernable curvilinear error distribution. Still different is the error curve for those who manage to approach the task without verbalizing it, for not only will they need more trials to eliminate their errors, but they also will usually show no peaking of errors near the midpoint of the maze. Such differences between subjects remind us that situations that can be verbalized provide especially rich opportunities for covert manipulations of materials by subjects, and require extra diligence and imagina-

tion by experimenters to control and/or analyze the effects of such individual styles of approach.

In at least one more way, studies of verbal learning entail complications not usually found in experiments of a nonverbal nature. Both the stimuli and responses used in most nonverbal experiments are sufficiently different from those encountered in situations outside the experiment that no great amount of interaction ordinarily occurs. Verbal behavior, to the contrary, is always with us, and these continual experiences almost always will influence performance in verbal-learning experiments (see especially, pp. 1122 ff.). Do we ask a subject to memorize a list of disconnected words? Prior experiences with such a list both color his reactions to them as individual items and determine his associations between them; previous use of the words may interfere with subsequent retention of the list; and experiences that intervene between the learning of the list and later retention tests will also distort the retention score. All these are complications that ordinarily can be ignored when we are working with nonhuman subjects or with situations that cannot be verbalized, for the stimuli and the responses involved in such experiments are not likely to be encountered anywhere except in the experimental sessions.

Having surveyed some of the more frequently encountered paradigms, let us now consider some of the concepts used in learning experiments and theory.

SOME GENERAL CONCEPTS

The Basic Units of Behavioral Analysis

With very few exceptions, the psychological analysis of behavior is based on units of stimulus and response. This point of view is a heritage of the physiology of the nineteenth and early twentieth centuries, during which the investigations of reflexes proved especially amenable to such analysis. The same point of view was carried over into the study of conditioning by Pavlov, and into other branches of behavioral investigation by psychologists in the early part of the twentieth century.

At first glance, it may seem obvious that responses are the outputs of organisms and stimuli are the inputs. The situation, of course, is far more complex than this simple statement would make it seem. For example, behavior is constantly being emitted by living organisms, and from this flux we attempt to dissect the relevant responses for further analysis. Similarly, there is continuous stimulation through multiple sensory channels, and although the experimenter may hold *his* source of stimulation constant, variations in the receptors and in other characteristics of the organism may cause changes in stimulation from one moment to another. Thus, to speak of "the stimulus" and "the response" is merely a convenient oversimplification.

The definition of stimuli Stimuli are sometimes specified in terms of energies presented by the experimenter. Thus, we say that one stimulus is a light with a certain distribution of wavelengths and another is a chemical solution of specified concentration and composition. Although it has been a matter of some importance to philosophers whether sensations may exist in the absence of sensing organisms, psychologists are not really interested in situations in which there are no organisms and thus do not find any great interest in this hypothetical question. On the contrary, a psychologist must be concerned with the question of reception of the energies he presents to the organism, for it is quite obviously possible for organisms to be insensitive to lights we present, or to be looking in another direction, or even to be gazing at a light without paying attention to its relevant dimensions. It *is* necessary to have a more elaborate specification of the stimulus than merely the description of its physical properties.

The position adopted by many psychologists has been clearly stated by Skinner (1935, 1938). Skinner argued that the definition of a stimulus ought not to be independent of

a demonstration of its correlation with specified responses. Thus we say the light is a stimulus if the subject says "I see the light," or presses a key which delivers the reinforcing stimulus only in the presence of the light, or in some other way shows by his behavior that the light has been detected. "Behavior" in this case is used in the most general sense to mean any changes in the functioning of the organism, and not just coordinated patterns of movements. For example, changes in neural activity (measured as changes in electroencephalograms or electroretinograms, for example), or in patterns of breathing or perspiring, may also be useful indices of detection of stimuli.

The definition of responses There are two basic ways to view the response term. The first of these may be thought of as *responses defined by consequences.* Consider, for example, the behavior of pressing a bar or a key: When the device is sufficiently depressed to close the switch, the apparatus defines the response as having just occurred, and the topography of the behavior which caused the switch closure is ignored. The value of such a consequence-derived concept of the response has been shown in countless experiments and practical applications. For example, if we wish to increase the probability of correct spelling of a word, we reinforce correct spelling whenever and however it occurs, and we disregard the movement characteristics of the behavior. The fact that orderly changes occur in responses defined in terms of consequences is the best evidence that such levels of analysis are psychologically meaningful.

On the other hand, there are situations in which the specific responses are of central concern, and a description and measurement of the pattern or sequences of patterns, and of the strength of the responses, then becomes the critical portion of the definition. The shape of an evoked potential, the raising of one paw rather than another, or the "clustering" of certain verbal responses are obvious instances in which the response must be examined in terms of its inherent characteristics rather than its consequences (see Hinde, 1966, pp. 9-12).

Levels of Explanation

In the most straightforward form of behavioral analysis, the experimenter presents or withholds one antecedent condition (see p. 3), observing the effects upon behavior each time the manipulation is made. From such experiments we can derive statements describing the importance of the presence or absence of the condition, but we cannot make statements about the functional relations between various values of the antecedent condition and the amount of change in behavior. Before we can make such a statement, it of course is necessary to present more than one value of the antecedent condition and, because organisms frequently are sensitive to the sequential effects of conditions, it usually is necessary to counterbalance the order in which the values of the antecedent condition are presented.

The history of most problems in psychology usually shows that experimenters first searched for significant variables, and that the functional relations of the variables and their associated behavioral effects were worked out later. For some students of behavior, the discovery of these functional relations is an appropriate endpoint. Still others aim to make their analysis on a more conceptual level, and attempt to abstract from the data more general concepts, some of which may make assumptions about the nature of processes which are not directly observable. Because we discuss some of these concepts in the following chapters, let us survey a few of those that are most frequently encountered.

Some Behavioral Concepts

Excitation and inhibition We have already encountered the concepts of excitation and inhibition. These terms have been borrowed from physiology, where they have reference to processes which underlie the occurrence

or nonoccurrence of reactions. For example, neural excitatory processes are those which excite other neurons, or give rise to muscular contractions or glandular secretions. Neural inhibitory processes, on the other hand, are those which work against the excitatory ones.

In behavioral descriptions, the terms have the same connotations: excitatory "tendencies" are those which lead to the occurrence of responses, except as they are blocked by inhibitory "tendencies." Excitation generally is associated with the effects of reinforcement; inhibition usually is associated with the effects of punishment or of nonreinforcement after prior reinforcement (extinction).

Note that the terms imply more than the mere occurrence or nonoccurrence of behavior: if that were all that were meant, there would be no need to use terms like "inhibition." Instead, these terms refer to hypothetical variables or processes to which theorists give *ad hoc* properties based on prior research, and which they hope will allow them to predict the outcomes of future experiments. Pavlov's (1927) excitatory and inhibitory processes (see p. 573), Hull's (1943) reactive inhibition (see p. 574), and Spence's (1936, 1937) excitatory and inhibitory effects (see p. 776 and Figure 17.11, p. 764) are well known examples of such theorizing.

Response strength The term *response strength* refers to the speed, intensity, or persistence with which responses occur. The term is not just a synonym for one of these dependent variables; it implies something more than is measured by any one of them. For example, Skinner (1938) spoke of the "strength" of an operant as it is reflected in response rate and in the number of responses emitted in extinction. However, because rate and resistance to extinction rarely are perfectly correlated, it is obvious that response strength must refer to something related to both, but identical with neither.

Response strength, then, is a low-level concept which is more general than any of the individual measures of behavior that we plot on the ordinate of figures. It has not been given formal theoretical status or development, but it is usually assumed that response strength increases with reinforcement and decreases with extinction.

Habit strength William James made "habit" a psychological term when he used it to label those very well practiced behaviors which keep each of us behaving in such highly predictable ways that habit becomes "the enormous fly-wheel of society, its most precious conservative agent" (1890, p. 121). Subsequent usage, however, has made habit the term for *any* learned response, no matter how thoroughly learned it might be.

Hull (1943) made habit strength one of the intervening variables in his theory of behavior, relating it on the antecedent side to the number of reinforcements,[22] and on the consequent side to the behavior measures of response latency, amplitude, probability of response in choice situations, and number of responses during extinction. Habit strength was to be scaled by observing the relations between reinforcements and responding, other factors (such as deprivation) being held constant.

When the term *habit strength* is used today, it usually is employed in a much less formal sense than in the Hullian system, but there still is the implication that the dimension referred to is habit ("learning") itself, and that other factors, as those of drive or incentive, are needed to turn habit into behavior. Here, then, is the primary difference between the concepts of "response strength" and "habit strength": the latter assumes a

[22] In *Principles of Behavior,* Hull (1943) had the limit to which habit strength could grow set by the quantity and quality of the reinforcer. In subsequent versions of his system (for example, 1952), he introduced a new *incentive* term which was sensitive to reinforcer characteristics, and let habit strength be determined solely by the number of reinforced occurrences of the response. This modification allowed the system to "predict" sudden shifts in speed or vigor of response when amount or quality of the reinforcer was shifted (see Chapter 15). Spence (1956) adopted a similar approach, but assumed that habit strength was determined by the number of times the response and the stimulus occurred contiguously, whether or not reinforcement occurred.

TABLE 14.5 TYPE OF EXPERIMENTAL DESIGN EMPLOYED WHERE A LEARNING-PERFORMANCE DISTINCTION IS SOUGHT

Drive or incentive condition	Amount of practice: Large	Amount of practice: Small	Differences attributed to motivation
High	a	b	(a+b) vs. (c+d)
Low	c	d	
Differences attributed to learning	(a + c) vs. (b + d)		

learning-performance distinction while the former does not take any special position on this question.

The learning-performance distinction Ask a child his name and he ordinarily will respond with alacrity, but if the question is repeated several times, there usually will be marked changes in the manner in which he responds—and after a few such repetitions he is quite likely to cease playing our game. However, we do not assume that his failure to continue saying his name reflects the loss of the ability to do so. This simple situation illustrates the nature of the learning-performance distinction that has played an important role in theories of learning. The distinction is a necessary one if it is assumed that (1) there is a state in which the effects of past experiences are coded and stored, (2) that it is this which is called "learning," and (3) that other factors (such as the child's exasperation when he is repeatedly asked for his name) modify the manner in which the learning is expressed but do not change the learning itself.

Many psychologists find it helpful to think of a model similar to those devised by Hull (1943, 1952) and Spence (1956), in which the effects of practice determine the learning (or habit) factor, whereas the final performance is determined jointly by a multiplicative relation of habit and motivational factors. Following this line of reasoning, it generally has been assumed that any indication of the separate effects of the habit and the motivational contributions to the final performance can only be estimated by using an experimental design in which at least two levels of amount of practice and two levels of motivational-incentive conditions are combined factorially. For example, imagine an experiment in which subjects are assigned to the four cells *a, b, c,* and *d,* each of which represents one of the possible combinations of practice and motivation (see Table 14.5). At the conclusion of the experiment, the differences between the sums of the columns would be taken as the reflection of the effects of the training and testing conditions on the habit factor while the differences in the sums of the rows would be said to reflect the differences in performance attributable to motivational factors.

The learning-performance distinction was introduced into experimental psychology during the 1930s, primarily as a consequence of the studies by Tolman (1932) and his associates, in which the effects on behavior of modifications in deprivation or incentive conditions were studied. The striking and sudden effects on behavior of changing the reinforcer from a less to a more highly preferred food seemed to contradict a view of learning which assumed that whatever responses occurred were direct reflections of "habits" or of "bonds" between the stimulus and response (Thorndike, 1913), for these generally were considered to be "relatively permanent." To explain rapid shifts in responding, the distinction between learning (the "bonds" or "habits") and performance (learning as activated by motivation) was in-

troduced, and it continues to be a distinction accepted by many investigators of learning. There are, however, many experimental and theoretical papers on the topic of learning in which this distinction is never introduced. For example, in much of the literature on verbal learning, in most of that on classical conditioning, and in almost all published papers on the analysis of operant behavior, the learning-performance dichotomy seems to be of little relevance.

THE GENERAL SCHEME OF A LEARNING EXPERIMENT

Once having obtained a fairly clear statement of the question to be investigated, the experimenter's next step is to decide upon the general *tactics* he will adopt in his experiment; the specific *method* he will employ, including the *subjects* to be utilized; and the *measures* of behavior which he will take.

Tactics of Experimentation

The term "tactics" was applied by Murray Sidman (1960) to the ways in which the experimenter behaves toward his experiments. By tactics, Sidman referred to the general orientation of the experimenter toward what he considers the primary problems of his discipline, and also the means by which he thinks those problems should be approached in the laboratory. Sidman was especially concerned with a description and analysis of some of the methods employed by those who study the behavior of individual organisms in depth, as contrasted with the methods typically used in the study of groups of organisms where each group is exposed to a separate treatment or set of conditions. Inasmuch as there is no one set of tactics which always will be superior to its alternatives, questions like those raised in the following sections must be considered each time we start an experiment.

Raw scores or averaged scores? Some of the earliest experimental studies of psychological problems (in sensing, perceiving, and psychophysics) found it necessary to average the results of numerous runs of an individual subject to obtain stable estimates of threshold values, psychophysical functions, and so on, and Ebbinghaus (1885) adopted this approach when developing his methods for studying human learning. Thorndike (1898) and Pavlov (1927), on the other hand, frequently presented the raw scores of individual animals, selecting for publication such sample records as (in their experiences) fairly represented the many experiments they had conducted.

At the same time, however, Galton (1883) was developing methods for describing the characteristics of groups of subjects, and Binet and Henri (1896) were devising techniques for obtaining average mental age values for test items. Thus, from the very beginnings of scientific psychology, all degrees of grouping and averaging of scores have been employed.

It seems that, as each new problem or technique was introduced into psychology, the earliest investigations concentrated on the study in depth of one or two individuals, but subsequent experiments frequently emphasized averaged, group data. The use of the multiple-unit maze is a case in point. Small (1899, 1900) constructed a scaled down replica of the Hampton Court maze, and observed the behavior of two rats in it under a variety of conditions. The data were largely qualitative, but they created an interest in this new technique for the study of learning, and within a few years there were many more published experiments using mazes. Most of these early experiments reported data derived from individuals only, but the variability of the individual animals was sufficiently large to discourage most attempts to see order in the data. Thus, averaged data gradually came to be used more and more to report the results of maze and discrimination experiments, as well as those of most verbal learning studies. Today it is relatively rare to find raw data or individual protocols used as other than illustrative materials. Still, many experimenters find their greatest satisfaction in obtaining sufficient control of their situations to allow the direct recording of publishable records. This has long been an objective of many physiologists and physiological psychologists (see, for example, Figure 4.8, page 96), and also has been a favored tactic of students of operant behavior (see, for example, Figure 15.19, p. 662).

One or several independent variables? An entirely new dimension of complexity was intro-

duced into the study of behavior when the methods devised by R. A. Fisher (1935) and others began to be adopted by psychologists. Basically, these methods (called "analysis of variance") allow the experimenter to compare the effects of several treatments and to estimate the probability that the difference between the means of the various sets of scores is attributable to chance fluctuations. These techniques also allow the experimenter to evaluate *interactions* of variables. For example, suppose we asked children to try to recall a list of words they had seen 1, 10, or 100 minutes earlier. Suppose also that we had some children who had high scores on an intelligence test, some who had average scores, and some who had scored below average. We could, by these techniques, decide whether the effects of the retention interval on recall depend in part upon the intelligence of the child.

The value of designs in which more than one independent variable is included is clear, but the danger in the use of such designs is also clear: In many cases, the experimenter is tempted to include just two values of a variable (presence versus absence, or high amount versus low) and, at the conclusion of the experiment, finds he can say only that a given factor does or does not have a statistically significant influence on the behavioral measure he employed. For the majority of psychological problems, such screening of potential variables may be an important preliminary step, but in many cases it is not so informative as a more thorough study of a single variable, yielding an orderly relation.

Individuals or groups? The argument about appropriate tactics sometimes seems to boil down to this question: Should we concentrate on observing the behavior of a few individuals for a relatively long time or a larger number of individuals for shorter periods? It has sometimes been implied that the control of conditions is better when the experimenter concentrates on a few individuals, but this is not necessarily true. Instead, the decision concerning the procedures to be employed should be based on the problem to be attacked. There are some problems that just cannot be investigated with one or the other of these types of designs, but there are also some problems that may be approached either way, and there are some problems that seem to need a combination of the approaches. An example or two may clarify this question. If we wish to know the functional relation of an antecedent variable and behavior, we ordinarily are concerned with the behavior of individuals, and thus we would seek the answer by running each individual through all of the conditions. For example, Keesey (1962) investigated the effects on the rate of self-stimulation of the amount of electrical brain stimulation per reinforcement (see p. 646). After implanting chronic electrodes in the brain of each rat he gave all of them sufficient practice in the self-stimulation situation to allow them to attain stable performance levels. On the basis of preliminary experiments, Keesey had decided that six different intensities would be sufficient to cover the working range of intensities. Preliminary experiments had also indicated that the rate at which the subjects would respond under any one of the conditions of stimulus intensity was influenced by the value of the stimulus immediately preceding. Therefore, a sequence of stimulus intensities was constructed which allowed each intensity to be given in every position in the sequence. This form of design (known as a *Latin square order*) allows the effects of the sequence of stimuli to be averaged out across the entire experiment. Note that the results from such a procedure do not eliminate sequence effects, but the averages of the individual observations provide a reasonable estimate of what the behavior might be like if there were no such effects due to the sequence of the stimuli.

The results for each of the ten animals showed the same general trend as the average values for the entire group (see Figure 15.14, p. 645). However, there were some rather marked differences in the response rates and the functional relations within the sample of ten animals, so that no one of the animals duplicated precisely the average results. This experiment illustrates some of the problems facing the experimenter who must decide which tactic to follow in his research. Where both individual and group data can be obtained, it is obviously of interest to do so.

It is also interesting to note the effects of repeating the procedure. In this portion of the experiment (which was also replicated with two other dimensions of stimulation), most of the animals increased their response rates on subsequent occasions, and most of them also revealed some decline in response rates at the higher intensities. Both these trends are faithfully depicted in the average curves.

How else might this experiment have been designed? Two extreme procedures could have been adopted. In one case, the experimenter could have assigned one group of animals to each

of the six intensities, giving the animals sufficient exposure to that intensity to allow their behavior to stabilize. The final results then would have been presented as an average curve drawn through the points for each of the groups. The disadvantages of this procedure are obvious. A relatively large number of subjects is needed, multiplying the amount of time needed for surgery and postoperative care; and the variability attributable to individual differences might make the validity of the group curves doubtful. For example, when Keesey's animals were receiving 3.0 mA the individual response rates varied from about five responses per minute to almost twenty-five responses per minute. Such variability in the absence of the evidence of the orderliness of the individual data might leave considerable doubt as to the effect the intensity dimension would have on the behavior of an individual if he were subjected to more than one intensity. (Incidentally, the procedure of exposing each of the separate groups of subjects to only one intensity might have produced an average curve which was flatter than the curves obtained when each subject was exposed to every value of the stimulation. At least, this is an implication of many other studies of reinforcer variables; see, for example, the discussion [pp. 631–641] of separate groups and within-individual designs as applied to the problem of amount of reinforcer; and Guttman, 1953; Grice & Hunter, 1964.)

Stable behavioral baselines An alternative design might have exposed one or two animals to all intensities, perhaps maintaining each set of conditions until some criterion of stable responding had been obtained. One of the inherent problems in this procedure is the difficulty in determining when responding has reached a sufficiently stable point to be considered as stable. Very often, if we run just one more session after some predetermined criterion of stability has been obtained, we will find the behavior straying beyond the limits we have set.

Instead of attempting to achieve stability of behavior at every intensity, it is sometimes more practical to attempt to regain the same "baseline behavior" between the sessions in which other variables are presented. In the experiment discussed above, one of the stimulus intensities might have been adopted as the reference point, a number of sessions at one of the other intensities might have been given until the variability from session to session seemed to have become acceptably small, and then the reference stimulus might have been reintroduced and maintained until the original (that is, the baseline) level of responding was once more obtained. In this way, sessions with the reference stimulus would have intervened between presentations of all the other values. This would allow the experimenter to be fairly sure that systematic changes in responsiveness were not occurring over the course of the experiment. (See the discussion by Sidman, 1960.) Unfortunately, baselines sometimes drift after subjects have been exposed to other variables, and this complicates the analysis of the data. Without following such a procedure, however, the drift might never be recognized! A far more serious limitation is the fact that, in many situations, there is likely to be a gradual shift in response rates toward an average value determined by the schedule of reinforcement (see below), and that this effect will gradually obliterate the effects of the variables under examination. Thus, the adoption of such a long-term procedure, involving repeated attempts to recover the baseline, may mask the importance of some variables, making this a less desirable tactic.

As we suggested in Chapter 1, there are some problems that can only be attacked by using independent groups, whereas others can only be studied by making extensive observations on an individual. In such cases, we obviously have fewer degrees of freedom available when designing the experiments. For example, there are the problems in which we can, as it is said, only skin the fox once. Familiar examples are those in which a treatment immediately changes the organism so that the baseline behavior could never be recovered and other values of the variable could not be applied. The effects of chronological age at time of imprinting or the influence of electroconvulsive shock at various times after completion of practice are familiar examples requiring separate groups of subjects at each age level or time.

However, we should not be too quick to assume that the procedure involving repetitive treatment cannot be applied to a given problem.

For example, we ordinarily assume that there can be but one uncontaminated test of the retention of previously learned materials, and that subsequent tests are influenced by the facilitating effects of the prior recall sessions. However, if we could devise a sufficient number of equivalent tasks, each could be learned and then tested for retention after varying intervals. This, of course, was the procedure used so successfully by Ebbinghaus (1885).

Similarly, it had been assumed for many years that stimulus generalization gradients could only be plotted from the data points obtained from separate groups of subjects at each of the stimulus values to be tested, since each test of generalization extinguished responding at that test point and thus provided discrimination training which distorted the hypothetical "pure" gradient. Generalization tests in which the same subject was tested at various points on the stimulus dimension (for example, Bass & Hull, 1934) were frequently thought to produce not a "primary generalization gradient" but the compound effects of generalization, extinction, and differential reinforcement. In recent experiments (see pp. 759-762), generalization gradients have been obtained from individuals by giving them prior training which minimizes the effects of extinction during the generalization test. The development of such procedures, which allow us to study gradients in the individual organism, have led to the discovery of valuable new phenomena such as the "peak shift" effect (see p. 778).

Methods of Experimentation

Most learning experiments utilize either the *free operant* or the *discrete trials procedure,* each of which has its own special advantages and liabilities. A few of the more general points about these procedures are discussed, and a description of a hybrid technique given.

In most cases, experimenters may choose their subjects from among several species, age groups, and so on. However, potentially important factors sometimes are overlooked in selecting subjects, and a few are described below.

Finally, some of the more common dependent variables in learning experiments will be considered, and a few of the means of presenting experimental results will be described.

Procedures employing trials The meaning of "trial" varies from one experimental situation to another. For example, in the Ebbinghaus procedure, a trial might consist of one reading through a list of words at a set rate of progress, or it might consist of one attempt to recall previously studied materials. In the first case, the word "trial" refers to a period of exposure to stimuli, while in the second it refers to a testing period. Both meanings also exist in the Pavlovian situation: early in conditioning, the trial consists of the presentation of CS and US; later in conditioning, a trial may be a test where CS alone is presented.

But even more confusion is possible! When training animals on a Lashley jumping stand (see p. 749), many experimenters follow Lashley in designating as *one trial* all jumps up to and including a correct response. Thus, one animal may make many times more *responses* than another, but because both have had an equal number of reinforcements, they are said to be equivalent in trials. For such reasons, comparisons of the efficiency of two procedures or of two types of apparatus should always include scrutiny of the definition of "trial" used in each situation.

When the experimenter arbitrarily breaks his practice sessions into trials, he interrupts the continuity of behavior. In many instances, this is of no consequence because the behavior is itself phasic, and/or it is securely under the control of known stimuli. For example, in the classical conditioning of the patellar reflex (Schlosberg, 1928), there is little probability that the reflex will occur at times other than following stimulation of the patellar tendon, and the experimenter need not fear that his procedure of scheduling separate trials is destroying any essential characteristic of the behavior. On the other hand, where the response in question has some free-running rate greater than zero, the decision about when to begin a trial may affect in significant ways the behavior being measured. For example, if the blink of an eyelid were the response being measured, the probability that

a blink might occur just at the instant that a trial is initiated is sufficiently large to have noticeable effects on results. For this reason, subjects usually are told to blink a few times and then get ready for the start of a trial, with the hope that the "spontaneous" blinks will thus be minimized during that trial.

The primary advantage of using a discrete trials procedure is that the experimenter maintains control of the spacing of responses. The primary disadvantage of the discrete trials procedure is that the behavior of the subject may be disrupted arbitrarily. Often special features are included in discrete trials procedures which reduce such disruption of behavior. One of these techniques involves the consistent presentation of some stimulus just before the trial is begun, which allows the subject to orient toward the relevant stimuli, and also alleviates some of the upset which might accompany sudden introduction of the trial stimuli. The opaque, vertically sliding door of the WGTA (see p. 750) comes to serve as a discriminative stimulus for responses of orienting toward the front of the chamber and assuming the posture for responding to the stimulus tray when the second (transparent) screen is raised. A similar function is served by the double doors separating the starting compartment from the alleyway proper in some straight-alley devices (see, for example, Logan, 1960). When the first door is raised, the thoroughly adapted rat investigates that end of the start box, and is in position to leave when the second door opens. In learning experiments involving humans, a "ready" signal serves the same purpose.

Free operant procedures The term *free operant* is used to describe procedures in which arbitrary discontinuities are not imposed on the behavior. Instead, a situation is arranged such that responses may be emitted freely, and the emission of each response leaves the organism free to initiate the next response. Although experimenters have long avoided interruptions during naturalistic observation, it is only relatively recently that they have tried to do so during the laboratory study of behavior (Skinner, 1932, 1956).

There are some who would say that "*free* operant" is redundant, but inasmuch as "operant" has become a synonym for "instrumental," it frequently is helpful to make an unmistakable distinction between those procedures which use trials and those which do not.

Self-paced trials A variant of the free operant procedure allows the initiation of each trial to be determined by the subject, but utilizes the discrete presentation of stimuli that is characteristic of methods employing trials. For example, we might allow the subject to set up the stimuli for the next trial by pressing a button, but the specific character (for example, the stimulus arrangements, or the duration) of each such trial would still be determined by the experimenter. These procedures provide such information as the percentage of presentations on which the correct response was made, which is difficult to obtain in the typical free operant experiment, and measures of the rate with which the organism initiates trials, which cannot be obtained when discrete-trial procedures are employed. Together with free operant procedures, the self-paced trial method shares the disadvantage of turning the distribution of responses over to the organism. Thus, where specific intervals of time must be maintained between presentations of stimuli, trials must be employed. (For a description of a self-paced procedure, see p. 682.)

The Selection of Subjects

It is not often that the experimenter has complete freedom to choose his subjects purely on scientific grounds. More frequently, his selection is limited by practical considerations of availability, economy, or ethics. Within these limitations, however, the experimenter frequently has a considerable choice open to him. But to the beginning student, it frequently must appear as though psychologists disregard the rich variety of organisms

and study only four species: man, monkey, pigeon, and rat. Of course, they occasionally use other species, but the majority of experiments have employed these four.

Actually, there are some instances in which the choice of subject seems to be of relatively little importance. For example, Skinner (1956) pointed to the similarity in the patterns of responding emitted by different species under certain conditions of intermittant reinforcement, and concluded that the choice of the species was not an important variable under these conditions. The data indeed support his contention, but it is more than a truism that we would never have known this interesting fact if different species had never been compared. Thus, one reason for using a variety of species is the discovery of similarities between them.

On the other hand, there are problems in which the choice of the species is crucial. The task of the comparative psychologist, according to Bitterman (1960) is the discovery of problems which do reflect species differences, and he has presented evidence that discrimination reversals and the effects of partial reinforcement on resistance to extinction are two problems of this type.

Why rats? In the psychological laboratory, the rat may seem to be preferred out of all proportion to its place in nature. There are, however, many reasons for utilizing the rat in psychological research. For example, the rat is a mammal, and as such it has many biological similarities to other higher organisms. Thus investigations of structural and functional characteristics of the rat have relevance for an understanding of behavior in a broad range of species. Furthermore, the rat is inexpensive, easily bred in captivity, and has a relatively short generation span. For example, the gestation period is only 21 days; the pups may be weaned after another 20 days, and the animals can safely be bred at the age of 8 or 10 weeks. However, even more important than all these practical matters is the fact that an immense amount of information has been accumulated on the anatomy, physiology, and behavior of the rat. This legacy frequently is not appreciated until the experimenter decides to use a new organism. He must then start more or less from the beginning to discover the conditions under which the animals may be maintained in good health and bred successfully in the laboratory, and the conditions that must be established if they are to survive surgery; he must discover for himself what the ranges and the limitations of the animals' sensory capacities are; and he must discover—by trial and many errors—what are the typical modes in which the animals respond in the situations he wishes to study. For these reasons there is considerable reluctance on the part of most researchers to give up the organisms with which they are familiar.

At the same time, it is now thoroughly established that our concentration on a limited range of organisms produces a correspondingly limited view of behavior. Certainly one of the more significant contributions made by ethologically trained investigators is the introduction into the behavioral literature of material from species previously ignored by psychologists (see Hinde, 1966).

Before leaving the topic of selecting subjects, it might be well to add a cautionary note about the assignment of subjects to experimental conditions. When such assignments are best done "at random" and when it is more efficient to try to construct matched groups of subjects is a complex topic better discussed in a textbook of experimental design than here. In general, however, it is true that there is more to be lost than gained by attempting to match subjects unless there is very good evidence that the basis on which the matching is done is really related to a significant degree to the behavior in which the experimenter is interested. For example, if we were to investigate the effects of presenting a lecture with and without accompanying illustrative slides on the recall of the material at the end of the course of study, it would not be to our advantage to try to construct two groups matched for intelligence because in most cases there would not be sufficient variation in the intelligence of the students participating in this experiment to allow intelligence to have a noticeable bearing on the recall scores. Instead, it

probably would be more efficient to construct two groups matched on the basis of a previous recall test because there usually is a strong positive correlation between the standings of students on one test and their standings on a second test in the same course.

It is obvious that if we were to assign (deliberately or by accident) all of the most able writers of examination papers to one of the two groups, the experiment would be seriously contaminated. In this case, common sense tells us to be wary of this kind of biasing, but there are other potentially biasing factors of which we are likely to be quite ignorant. Wherever this is the case, a random assignment of subjects to groups is usually adopted in the hope that the differences among subjects will be distributed more or less equally across the groups.

"Random assignment" in the practical situation means that the probability that a subject will be assigned to one group is equal to the probability that he will be assigned to any other group. To achieve this end, experimenters frequently use published tables of "random" numbers to decide which subject to assign to which group. We cannot substitute for such procedures the scattering of subjects across conditions by whim or by accident. Returning to our simple experiment involving two groups, it would not be sufficient for the experimenter to assign every second subject to the lecture in which no slides are shown, nor would it be "random" if he were to assign subjects by saying "Group A, Group B . . ." and so forth in what he thinks is a random sequence of As and Bs. Both of these methods introduce bias, the one because alternate assignment might not equally distribute characteristics which might influence the experiment, and the other because the experimenter cannot call out a sequence of events which approaches a random sequence. Instead, almost all of us tend to balance up the strings of letters or numbers when we try to behave as a random generator, forgetting that in truly random series there frequently are long runs in which the individual items are grossly out of balance (Solomon, 1949).

Another form of biasing sometimes creeps into the assignment of animals to groups or conditions. Imagine that a shipment of animals has just been received from the supplier and that all the animals now are in one large cage or pen. If the first animals withdrawn from the pen are assigned to one group and the second batch assigned to another group, almost certainly the assignment will be biased, for the easiest animals to withdraw from the enclosure are usually quite different in a number of ways from those which are the last to be caught. The safest way to avoid such biasing is to number each animal as it is obtained, and then use a random number table to assign these animals to the conditions of the experiment.

Schedules of Reinforcement

After he has decided the broad outlines of his procedure and the selection of his subjects, the experimenter must next decide whether his procedure will involve reinforcement of every response, or whether only a portion of the responses will be reinforced. If the latter option is selected, it is also necessary to decide which rules to follow to determine what responses are to be reinforced. These rules are called *schedules of reinforcement*. Familiarity with a few of the basic schedules and their characteristic effects is essential to an understanding of the behavioral literature. We here mention just some of the more obvious facts about schedules (for greater detail, see Honig, 1966; illustrative data and descriptions of procedures will be found in Ferster and Skinner, 1957).

Continuous reinforcement If every correct response is reinforced, the schedule is said to be one of continuous reinforcement (CRF). This is typically the procedure employed at the start of training; rapid increases in response rate ordinarily are obtained at the very outset, and resistance to extinction is minimal. If the rate of response is to be used to evaluate the effectiveness of treatments or conditions of reinforcement, CRF is not to be recommended. The first disadvantage of CRF is the inordinate proportion of the total time that is spent in consummatory behavior, leaving little time for the operant responding and hence a relatively small range over which response rate may vary. The second disadvantage is the rapidity with which satiation may occur when every response is reinforced. Of course, such difficulties will not arise when a reinforcer is used that does not involve time-consuming consummatory responses, or one with which satiation is no problem. Posi-

tively reinforcing electrical brain stimulation or negatively reinforcing foot shock are two common examples of reinforcers that meet these requirements.

Ratio schedules Instead of reinforcing every response, it sometimes is preferable to reinforce some, thus making the ratio of responses to reinforcements something greater than 1 : 1. There are two types of ratio schedule in common use. In the first, a fixed proportion of responses is reinforced. If every tenth response were reinforced, the schedule would be described as a fixed ratio 10 (or FR 10). Responses may also be reinforced after varying numbers of responses have been made. In this case the schedule is described as a variable ratio (or VR) schedule of reinforcement. Unless otherwise specified, it is safe to assume that the numerical value given for a VR schedule is the arithmetic mean.

Ratio schedules characteristically generate high rates of responding in free-operant situations as long as the numerical values of the ratios are relatively small. What constitutes a "relatively small" ratio is dependent upon the organism and the situation. For example, ratios of 100 in a lever pressing situation might be relatively small for man or rhesus monkey, moderately large for a pigeon or a six-year-old child, and very large for a rat or a human of toddling age (see Sidman & Stebbins, 1954; Ferster & Skinner, 1957; Long, Hammock, May & Campbell, 1958; Weisberg & Fink, 1966).

The FR schedule typically produces a pattern of responding which shows a post-reinforcement pause followed by a steady response rate until the next reinforcement is delivered. As long as the conditions of the experiment are held constant, this response pattern remains relatively stable. As the ratio requirement is increased, the post-reinforcement pause is lengthened and the response rate is depressed. If the ratio requirements are held constant and deprivation (or other motivational) conditions are increased, the post-reinforcement pause is decreased (see Sidman & Stebbins, 1954; Ferster & Skinner, 1957). With VR schedules, post-reinforcement pauses and "go—no-go" response rates are also seen, but interruptions of responding frequently occur at unpredictable points (Ferster & Skinner, 1957) making VR a less satisfactory schedule for many purposes than FR. Since ratio schedules characteristically generate high response rates, they are useful tools for the analysis of the effects of various treatments on behavior, where we want to determine whether the treatment might have impaired the coordination or the vitality of the organism.

Interval schedules Parallel to the fixed and variable ratio schedules are fixed and variable interval schedules of reinforcement. When using a fixed interval (FI) schedule, we reinforce the first response that occurs after each predetermined unit of time. If, for example, the first response after every four minutes were to be reinforced, the schedule would be described as FI 4 min. The variable interval schedule reinforces the first response after intervals of time that vary according to a prearranged program. Unless otherwise specified, the numerical value of a VI schedule is the arithmetic mean of all of the intervals. In selecting intervals, ordinarily an attempt is made to include at least a few short intervals so that responses emitted soon after each reinforcement will sometimes be reinforced, thus making long post-reinforcement pauses unlikely. (For a discussion of the selection of intervals, see Ferster and Skinner, 1957.)

The typical behavior pattern generated by VI conditions is a steady response rate. Such steady responding is a useful base against which we can compare the effects of conditions of reinforcement, deprivation, or drug or surgical treatments. However, if a VI schedule is maintained for many sessions, the schedule itself determines the response rate and may override the effects of the variables in which we are primarily interested (see Keesey and Kling, 1961, for an example of this effect; see also a discussion of the "locked rate," by Ferster and Skinner, 1957).

When fixed interval schedules are first applied, there may be a short period during which small extinction curves are seen. This usually is followed by a period during which consistent response rates are emitted; these steady response rates then give way to patterns that show a post-reinforcement pause and then gradual acceleration in rate until the next reinforcement is delivered. These "scallops" or periods of positive acceleration are easily disturbed by changes in the conditions of the experiment and hence are a useful index of the extent to which the variations are detected by the organism.

Reinforcement of interresponse times The analysis of interresponse times (IRTs) provides a more detailed picture of the effects of reinforcement schedules (and other antecedent conditions) than does the mere inspection of the overall response rate (see Figure 15.15, p. 648). IRTs can also be directly reinforced, thus bringing the momentary rate of response under experimental control. For example, we might set an interval timer so that it programs a reinforcement if 30 seconds elapses without the occurrence of a response. IRTs shorter than 30 seconds reset the timer, thus postponing the next reinforcement. In comparison with most schedules, this procedure produces low average rates of responding, and is therefore called "differential reinforcement of low rates," or DRL.

In addition to establishing the rule that any interresponse time exceeding some selected value will prime the reinforcement circuit, we also can establish a "limited hold" contingency which sets an upper bound on the period during which reinforcement is available. If, for example, we were to add a 5-second limited hold to our DRL 30 sec. schedule, only IRTs of more than 30 seconds and less than 35 seconds would result in responses being reinforced.

Organisms can be brought under quite tight control with such schedules, allowing the experimenter to determine not only the average response rate but also to control with considerable precision the momentary rate of response (see Anger, 1956; Morse, 1966).

More complex schedules The simple schedules may be combined in various ways to produce complex schedules suitable for the direct analysis of behavioral or physiological problems. Although the description of even the more common complex schedules is beyond the scope of this volume, an illustration may convey some impression of the value of these techniques.

Suppose we wish to train our subjects to differentiate two stimuli, perhaps as the initial stage of an experiment to determine the limits of their abilities to discriminate between stimuli. After initially shaping the desired response (for example, lever pressing), and a short period of CRF to establish the response, we then might introduce a VI reinforcement schedule and thus generate relatively consistent response rates with relatively few reinforcements. Now we might add periods of extinction to the schedule, so that extinction and variable interval reinforcement occasionally alternate, pairing one of our stimuli with the VI periods and the other with the periods of nonreinforcement. Such schedules, in which two or more simple schedules are combined, with each unit having a correlated discriminative stimulus, are called *multiple schedules* and are frequently used to study discrimination, generalization, sensory thresholds, and similar problems.

Imagine that we found that the typical effect of this procedure was to produce fairly high and steady response rates in the presence of the stimulus correlated with the VI component and much lower rates when the stimulus correlated with extinction was present: Would we be warranted in concluding that the stimuli were actually discriminated and that they were controlling the different response rates? At least one other possibility would first have to be eliminated, for it is conceivable that our subjects were discriminating the presence and/or absence of *reinforcement*, responding relatively slowly until

a response was reinforced and then responding rapidly until a long period of nonreinforcement was encountered. To minimize such differential behavior based on the discrimination of the underlying pattern of reinforcement and extinction, several procedures have been devised. For example, by insuring that relatively variable periods of each schedule (VI and EXT) are interwoven, and that the change from one schedule to the other never is made immediately following reinforcement, the probability of "outguessing" the schedule is greatly reduced. However, even in such cases, animals and children can discriminate at least some of the underlying pattern of reinforcement, and the only way to determine just how successful they have been is to remove the discriminative stimuli altogether, and let them work on the underlying *mixed schedule* until they have achieved their best possible performance. By comparing this with the response rates in each segment of the multiple schedule, the extent to which the discriminative stimuli themselves control the behavior can be estimated. (See Ferster and Skinner [1957] and Sadowsky [1970] for some characteristic results of such experiments; also see Blough [1966] for a discussion of the applications of the results to animal sensory processes.)

Partial reinforcement effects Any schedule of reinforcement other than continuous reinforcement is, by definition, a partial reinforcement schedule. As a general rule, a subject is more likely to continue to respond during periods when it does not receive reinforcement if, during prior training, it received only partial reinforcement rather than continuous reinforcement. This phenomenon is called the "partial reinforcement effect" (see reviews by Jenkins & Stanley, 1950; Lewis, 1965). Resistance to extinction is only one of the ways in which different degrees of response persistence can be observed; persistence in emitting the formerly reinforced response when a discrimination has been "reversed" (that is, when the formerly incorrect response is made the correct one, and vice versa) and the extent to which the subject persists in making a response in the face of aversive stimulation also show the same general relationship: Partially reinforced responses are more persistent than responses that have been continuously reinforced.

The schedule of partial reinforcement determines the *pattern* as well as the overall persistence of the behavior during extinction. Following variable interval reinforcement, behavior during extinction usually continues to be emitted at a regular rate, declining slowly as extinction continues. After fixed-ratio reinforcement, on the other hand, responding usually is emitted in streams having quite constant rates, but the pauses between such bursts of responding increase in length, and the bursts become shorter as extinction continues. These behaviors seem to suggest that the stimulation resulting from the organism's own responding plus that from the presentations of reinforcers serve as discriminative stimuli for the further emission of responses. For example, with variable interval reinforcement, responses are reinforced when they have been made after varying intervals, thus allowing varying numbers of nonreinforced reponses and various periods of nonresponding to preceed the occurrence of the reinforced response. Thus, almost everything that the subject can do (respond, pause, engage in displacement activities) has at some time in his past history been followed by the next response being reinforced. Therefore, almost anything the subject does sets the occasion for (that is, produces the discriminative stimuli for) his making yet another response, and so great persistence is produced.

The patterns of responding characteristically generated by reinforcement schedules are the same for members of many species. For example, the characteristic fixed ratio pattern of a post-reinforcement pause followed by responding at a constant rate until the next reinforcement, is seen in humans of various ages (see, for example, Long,

Hammock, May & Campbell, 1958; Weisberg & Fink, 1966), as well as other mammals (see, for example, Sidman & Stebbins, 1954), and birds (see, for example, Ferster & Skinner, 1957). However, when more primitive organisms are used as subjects, we no longer see this pattern. Indeed, when fish are used as subjects the partial reinforcement effect itself seems to be obtained only if massed trials are employed. This suggests that at this level, organisms may be incapable of responding to cues from presence *vs.* absence of reinforcement except as they are conveyed through immediate sensory carryover from one trial to another (Gonzalez, Behrend & Bitterman, 1965).

Common Response Measures

Response rate One of the most frequently used dependent variables is the rate of emission of a response. This is the basic datum in the free operant situation (discussed above). The advantages of response rate as a datum are several: as it is ordinarily observed, response rate can vary over a wide range; it can change quickly in response to changes in experimental conditions; and if the subjects are properly trained, very stable response rates can be obtained. These are not inconsequential advantages, as anyone will realize who has worried over the sometimes disturbingly large fluctuations in response latencies or running times when discrete trial procedures are used. Moreover, changes in rate are directly observable, while changes in some of our other dependent variables (such as percent correct responses) may only be revealed after much data has been collected and analyzed.

Response rate, of course, is not without its limitations as a datum. There has sometimes been concern because the overall rate is an average of a variety of local rates (Verplanck, 1950). For example, while responding at a more or less steady rate of fifty pecks per minute, a pigeon may emit some pecks which follow the preceding one at a tenth of a second and other pecks which have interresponse times of only a hundredth of a second. This, however, may also be seen as an advantage for rate as a measure, since there is the immediate averaging of these momentary responses (a process which has been likened to the averaging of movements of particles in a gas which produces the average pressure of that gas; see Honig, 1966). On the other hand, rate itself is conditionable, which sometimes reduces its utility as a dependent variable.

Of course, there are some processes which are just not amenable to study with rate as the dependent variable. Most of the phenomena discussed in Chapters 19, 20, and 21 are concerned with the emission of single responses, and response rate in those circumstances has little relevance.

Amplitude or vigor of response Although this was the primary datum in Pavlov's (1927) experiments, contemporary research makes relatively little use of these measures. In part this may be a consequence of the difficulties encountered when measurement of the amplitude or vigor of responses must be made. However it also reflects the current interest in problems that are more readily approached by observing other aspects of behavior.

Response latency One of the more frequently utilized measures is the latency with which a response occurs after the opportunity for the response is given. Like other time-based measures, latency has the advantage of being measured in units which are universally appreciated and clearly specified.

Response latencies almost always have skewed distributions, since there is some absolute level below which they cannot possibly fall while there is almost no limit to how long it may take for the response to occur. Because the mean is so sensitive to extreme scores, response latencies are either transformed to reduce skew before averaging, or else the median is used as the measure of central tendency. The most commonly used transformations are the reciprocals or the logarithms of the latencies.

Response times (such as running times in

mazes or alleyways) usually produce the same kind of skewed distributions. The reciprocal of the running time is, of course, a speed measure, and in addition to making more intuitive sense than does the logarithm of running time, it also allows us to make some comparison across experiments, as when all scores are converted to feet per second.

The Problem of "Learning Curves"

The general problems of presenting the results of experiments are much the same for all areas of science: the data should be presented as clearly and succinctly as possible and related to other findings so that readers can see the relevance of the results.

On the whole, graphical presentations of results are both economical and forceful ways of summarizing data; they also help the experimenter see trends or relations in his results that he might otherwise miss. In general, if a curve summarizes changes in behavior over successive practice periods, it is called a "learning curve." Almost all the curves we find in the literature on learning are just the results of variations in a few basic procedures. Some of the more frequently used procedures, and the assumptions underlying their use, are summarized below.

Classical learning curves The standard procedure is to plot the results of each trial against the trial number, placing the units in which the behavior is measured on the ordinate, and trials on the abscissa. As long as the behavior being depicted is obtained from a single subject, no problems of interpretation are raised: The curve merely summarizes for the eye what the data sheets contain.

This type of curve was frequently published in the earliest learning experiments (see, for example, Thorndike, 1898, 1911), depicting the time per trial to complete a task (for example, to escape from a puzzle box or traverse a maze). Such experimental situations offered so little control over conditions that there was almost always considerable variability in the data. To provide an estimate of what the "real" curve would look like under the hypothesized ideal conditions, various averaging procedures were introduced.

One type of average is obtained by combining scores from adjacent trials. For example, instead of plotting the time per trial, the average for blocks of two or more trials is used. Although this form of averaging loses detail, it does smooth out some of the irregularities and makes the more general trends easier to see.

Another type of average may be obtained by repeating a procedure several times and taking the average of the repetitions. This process introduces a new complexity, for it is based on the assumption that the average curve fairly represents the individual curves that went into it. If the individual curves are obtained from one subject who is run through a procedure several times, it is assumed that the functional relations obtained from the several runs are the same; if the average is based on curves obtained from several different subjects, it assumes that their curves are comparable.

For many years there was considerable interest in the form of "the learning curve," with the assumption being that the acquisition of behavior would always follow the same course, except for uncontrolled variability. This question has never been settled; the problem proved to be an unfruitful one, and interest in it has waned. However, while it was an active topic, many arguments over the most appropriate way of plotting curves appeared in the literature and eventually generated some "backlash" from writers who argued that nothing definite could be told about the behavior of individual subjects from group learning curves (see, for example, Sidman, 1952). This is not quite true: the average curve can be used to test the hypothesis that the individual functions are of a certain form (Estes, 1956). Of course, it is still necessary to assume that all the individual data going into the averages are comparable.

Cumulative response curves If the units of behavior are allowed to accumulate over the observation periods, a cumulative curve is produced that has certain advantages over
Figure 14.7. Comparison of two procedures for presenting results. The panel on the left contains a segment of a record obtained from a cumulative recorder. The paper is fed through the recorder at a constant speed; each response moves the pen a fixed distance across the paper. Thus, the rate of response is shown by the *slope* of the curve. The pen automatically resets to the baseline at some preselected point (in this case, after 500 responses). The same responses were also indicated on electromechanical counters, and those counts are plotted in the panel on the right. The results show the effects of training a pigeon with different amounts of food per reinforcement. The bird was occasionally reinforced (on the average, once per minute) for pecking an illuminated key. The color of the key indicated which reinforcement condition was in effect. Reinforcements consisted of delivery of either 1, 4, or 8 hemp seeds. The reinforcement condition changed every four minutes. Occurrences of reinforcements are shown by slight oblique marks on the record. Among the advantages of the cumulative record are instant information concerning the progress of the experiment, and an indication of the sequential changes in the behavior. The plot of responses trial-by-trial (or minute-by-minute in this case) allows the dependent variable to be read with greater ease: in the first minute of this experiment, for example, it is clear from the right panel that the average response rate was approximately 14 pecks per minute, but it would be difficult to determine this from the cumulative record. In practice, both cumulative recorders and digital counters are usually used, since each form of recording has its own advantages. (Data from an unpublished experiment of the author.)

the trial-by-trial plots. For example, we can read changes in response rate directly from the curve, and minor fluctuations around the dominant trend are less likely to be distracting. Figure 14.7 shows how the same data appear when plotted in the trial-by-trial manner and as a cumulative curve. Note the effects on these two plots of the same changes in the data: If scores remain the same over several observation periods, the cumulative plot has a constant slope, whereas the trialwise plot proceeds parallel to the base line; where scores decrease, the cumulative curve decreases *in rate of increase,* while the trialwise plot drops; and where scores increase, the cumulative plot shows increasing slope, while the successive trials plot rises. Of course, the cumulative curve can never decrease over time; even if the subject stops responding altogether, the curve only flattens.

In experiments in which response rate is the primary datum, cumulative records of responding usually are recorded "on line," to give immediate information concerning the
Figure 14.8. One way of constructing a Vincent curve. The rationale of the process is as follows: Along the baseline, the initial trial is numbered zero, and the total number of trials required to attain the performance criterion is called 100 percent, whatever the total may be for any subject. Along the ordinate, the score on the original trial is called zero, and the score on the occasion when criterion was reached is called 100 percent.

In the present example a maze is learned by two suppositious rats, A and B. Rat A makes 20 errors on his first trial; since this is his worst performance, we say he has "20 errors to eliminate," and thus each error eliminated would be 5 percent of his total. Rat A reaches criterion 11 trials beyond the initial (zero) trial, each trial thus being approximately 9 percent of the total trials needed. Rat B starts with 33 errors to be eliminated, each error thus being 3 percent of the total to be eliminated if he is to reach the criterion of an errorless run. Since Rat B reaches criterion in 17 trials, each trial is approximately 6 percent of his total. The *x* and the *y* values for each point on the A and B curves are computed as follows:

Subject A					Subject B				
Trial	*x*	*Errors*	*% errors*	*y**	*Trial*	*x*	*Errors*	*% errors*	*y**
0	0	20	100	0	0	0	33	100	0
1	9	18	90	10	1	6	23	69	31
2	18	15	75	25	2	12	18	54	46
3	27	12	60	40	3	18	16	48	52
4	36	10	50	50	4	24	13	39	61
5	45	10	50	50	5	29	11	33	67
6	55	8	40	60	6	35	8	24	76
7	64	5	25	75	7	41	10	30	70
8	73	4	20	80	8	47	7	21	79
9	82	2	10	90	9	53	8	24	76
10	91	1	5	95	10	59	5	15	85
11	100	0	0	100	11	65	2	6	94
					12	71	4	12	88
					13	76	1	3	97
					14	82	2	6	94
					15	88	1	3	97
					16	94	1	3	97
					17	100	0	0	100

*$y = 100 - \%$ errors

When the A and the B curves have been drawn, the base line is divided into ten equal parts, perpendiculars are erected, the ordinates of A and B are measured on each perpendicular, and a point on the Vincent curve is obtained by averaging the A and B ordinates. The linear interpolation can, of course, be done arithmetically instead of graphically. (Woodworth & Schlosberg, 1954.)

behavior of the subject. The generic term for devices that write out such records is "cumulative recorder." Essentially, they consist of a constant-speed paper-feeding mechanism and a device to move the recording pen a given distance across the paper each time an input is received.

Vincent curves Occasionally it is necessary to construct an average curve to represent the behavior of individuals whose progress through the experiment is grossly dissimilar. For example, one subject may require twice as many trials as another to memorize a list of words, and if we were to take the mean of their scores at each trial, the resulting curve would look like neither of the individual ones. One way of eliminating the effects of such differences in plotting group curves was originally suggested by Vincent (1912) and is still called the Vincent curve although the procedures most likely to be used today have been much modified by later users (see Munn, 1950, pp. 226–230).

The rationale for the Vincent curve is simple: Disregard the actual number of trials needed by each subject to complete the task and plot his results in terms of the percentage of the total number of trials that is represented by each trial; disregard the actual number of errors per trial, and plot his progress in terms of the percentage of his own total errors which are eliminated on each trial. The average curve is then based on these "percentage" curves (see Figure 14.8).

The logic behind Vincent curves is that subjects can be compared when they are at proportionally equivalent points in terms of total practice time needed, total errors to eliminate, and so on. Obviously, the way to tell if this is a warranted assumption for any particular experiment is to examine the data after treating it in this manner.

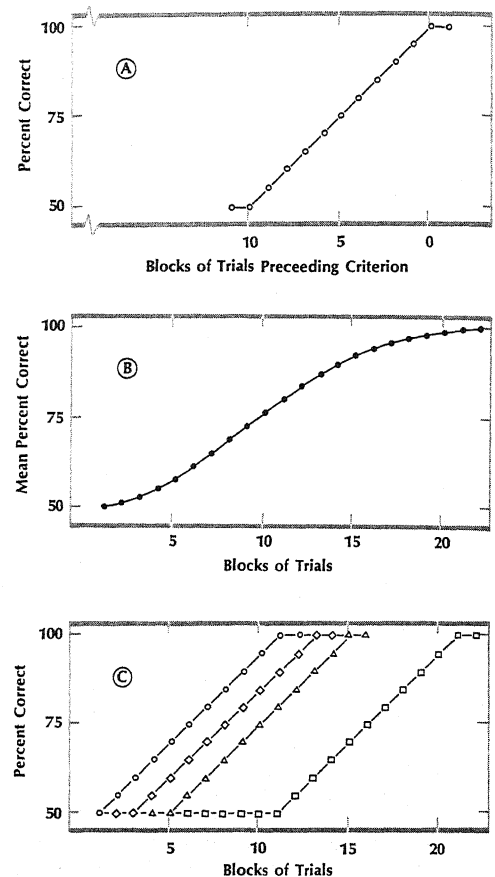
Traditional Vincent curves are not used very frequently, but "adjustment" of the results for individual organisms along one or the other axis for purposes of plotting results is quite frequently employed. For example, we


Figure 14.9. Comparison of a learning curve showing average errors with a backward learning curve. Four suppositious subjects are given training in a two-choice discrimination task. Each subject begins to eliminate errors at a different point in practice, but once improvement begins, it is at the same rate for all subjects (Panel C). The mean curve for these subjects (Panel B) is sigmoid rather than linear, suggesting a degree of gradualness of improvement that is absent from the individual data. The backward learning curve (Panel A) is constructed by noting the point where the criterion was met, and then working backward, determining the percent correct for each block of trials. The average percent correct for 1, 2, 3 . . . N blocks of trials preceeding criterion is thus determined. If the curves in Panel C were those of four *groups* of subjects, the backward learning curves would be anchored at the median trial on which members of each group attained criterion.

might disregard the actual number of trials taken during practice and plot the results against the number of reinforcements, on the assumption that the behavior measured is most likely to be modified by reinforcements and to be left essentially unchanged by trials on which no reinforcement occurred. (For an example of such a curve, see Figure 21.36, p. 1124.) Or, we might assume that comparability of performance should be the basis for selecting the points at which our subjects will be matched; the plot of the results from such a procedure has been called a "Melton curve," and ordinarily it is constructed by averaging the number of trials needed by each subject to attain equivalent performance criteria, such as 25, 50, 75, and 95 percent correct (see Melton, 1936; Melton & von Lackum, 1941).

Backward learning curves In the curves just discussed, the anchor point is the start of practice. But imagine a learning task in which every subject begins to make progress at a different time, but that each then progresses at the same rate. A curve of the average of the results from such data will have less slope than any individual curve, and it will show an initial period of positive acceleration which also is lacking in our hypothetical individual curves. Hayes (1953) suggested anchoring the individual curves at (or near) the end of practice, so that the differences in the initial periods could be discounted.

Although there are several variations of the procedure, the general plan followed when constructing such curves is to work backward from the final performance, computing, for example, the percent of correct responses at the last trial, the next-to-last trial, and so forth (see Figure 14.9). Such curves cannot tell us the average accuracy for the group on any specific trial, but they can be used to find the average accuracy on any given number of trials before the performance criterion (or whatever else was used to establish the final level at which all curves were anchored). Backward learning curves have been valuable tools in analyzing the rate of progress, once it has begun, especially when different degrees in the difficulty of discriminations or different complexities of tasks are involved (see, for example, Shepp & Zeaman, 1966).

J. W. Kling and Allan M. Schrier

POSITIVE REINFORCEMENT

15

Before beginning a chapter on the topic of reinforcement, we are obliged to deal with some problems of terminology. Three terms in common use—"reinforcer," "reward," and "incentive"—sometimes are used interchangeably and sometimes are not. Their meaning is changed by each investigator, as well as from one year to the next. Furthermore, the term "reinforcement" is often used in the sense of "reinforcer" and, hence, also confused with "reward."

We define a reinforcer as the thing (such as a piece of food or a sexual partner) that alters the probability of reoccurrence of, or otherwise strengthens, the response that produces it. "Reinforcement," then, will refer to the presentation of a reinforcer. When the terms are used in this manner, it should be kept in mind that reinforcement is not a thing: We do not present a reinforcement—we present a reinforcer.

As generally used, "reinforcer" and "reward" seem to have practically the same meaning, and there do not seem to be any overwhelmingly compelling reasons to choose one of the terms over the other. Some experimenters object to "reward" because it is derived from the language of everyday life and carries with it connotations of something pleasant and good which it seems best to avoid in the laboratory. Others point out that "reward" in other than psychological situations refers merely to that which is bestowed for actions approved by the donor and does not

necessarily connote any special influence on the behavior of the recipient. Thus, where we wish to have a term which is neutral in terms of subjective impressions, and which has as one of its defining properties the "strengthening" of a response, "reinforcer" seems the term of choice. Of course, reinforcers may be pleasant when we experience them, or they may consist of the termination of events we would label noxious, or they may be completely outside our realm of experience (such as electrical brain stimulation, which proves to be reinforcing). Sometimes they will even be events which "make no sense" to us, as when the frequency of a response emitted by laboratory rats is increased when each response is followed by the *onset* of mild electrical foot shock (Harrington & Kohler, 1966). Trying to make predictions of the possible reinforcing properties of events from our own experience can be hazardous, even when fairly familiar situations are involved: The phrase "generation gap" is a recognition of the differences in the events which are reinforcers for various age groups, and "culturally deprived" often means "his reinforcers are not mine. . . ." On the practical level, determining what constitutes a reinforcer is one of the most important tasks required of the therapist, teacher, or parent; at the present time, the behavioral test for reinforcing properties of events is the only solution to these problems, just as it continues to be the final test for the laboratory worker.

Although some experimenters object to the term "reward," others object to the terms "reinforcer" and "reinforcement" because they feel these terms may have unintended theoretical implications. The definition of reinforcement we have already offered refers strictly to empirically determined relations between events: In the presence of certain stimuli, responses become more likely when they have been followed by certain events (reinforcers) and become less likely when they are no longer followed by these events. However, something underlying the observed empirical relations between events has been implied by these terms in certain theoretical contexts. Some years ago, for example, the most prominent theory of learning (Hull, 1943) maintained that a reinforcer always was a drive (or drive-stimulus) reducer. Today, however, "reinforcer" and "reinforcement" rarely refer to anything more than the empirical observations. We feel, therefore, that these are the more desirable terms, and use them exclusively in the discussions in this chapter.[1]

This leaves the term "incentive" in need of clarification. "Incentive" sometimes has a meaning that is rarely implied by reward and reinforcer and which certainly deserves a special term. This meaning has recently been stated by Logan (1960):

> "Incentive" is a hypothetical concept referring to what might popularly be described as the subject's expectation of reward. If a rat's performance in an alley is differentially affected by the reward he has previously received in the goal box, then some internal consequent of the reward must be present while he is in the alley before the reward is received. "Incentive" is . . . [the] . . . word for this consequent [p. 3].

For example, even though the experimenter might hold the amount and quality of the reinforcer constant over a series of trials, incentive might be changing. We restrict the term "incentive" to this meaning suggested by Logan (1960). (The concept of "incentive motivation" is discussed in Chapter 18.)

QUANTITATIVE VARIATION IN REINFORCERS: THE "AMOUNT" PROBLEM

Typical Manipulations Defining "Amount" and the Problems Raised by Them

Once it became apparent that the reinforcer was an important determinant of be-

[1] For a discussion of some of the theoretical issues which have played a role in shaping the use of "reinforcement" in psychology, see Hilgard and Bower (1966). The term was originated by Pavlov and referred to the pairing of a neutral and an unconditional stimulus in the conditioning situation (and thus, the pairing of the reflexes associated with each stimulus). The "positivistic" concept of the reinforcer now so much a part of psychological literature stems largely from Skinner's writing. A concise summary of this point of view can be found in Skinner (1953, especially Chapter 5).

havior, it was quite natural that researchers should begin manipulating parameters of the reinforcer to determine their effects. In the earliest experimental studies, variations in amount and type of food were investigated (see, for example, Simmons, 1924; Elliott, 1928, 1930; Grindley, 1929). For example, Simmons found that a group of rats fed a bite of bread and milk in the goal box of a maze showed, on the average, better maze performance than rats fed sunflower seeds. Of course, in these studies, many of the parameters of the reinforcer were allowed to vary at once.

Two potentially important dimensions of reinforcers were separated by Wolfe and Kaplon (1941), when they distinguished between the effects of the amount of food and the amount of "consummatory responding" involved in goal box activity.[2] They gave three groups of chicks three behavioral tests (straight runway, detour or "umweg" runway, and black-white discrimination), reinforcing one group with a single, whole piece of popcorn, another with four one-quarter pieces of the corn, and the third group with one of the quarter pieces of corn. The first and the second groups, of course, ingested equal amounts of food, whereas the first and third groups engaged in equal amounts of consummatory activity (a single peck). In all three tests, the group reinforced with the four one-quarter pieces was superior to the others in speed of running and error elimination.

Because the variability of the speed and error scores was rather large, and because the same groups were used in all three experiments, it is difficult to decide how reliable an effect was produced by differences in the amount of food per se, or by the amount of consummatory responding. Nevertheless, the study suggested quite strongly that the total reinforcing effect should be considered in terms of the behavior the organism emits in the presence of the reinforcer, as well as in terms of the sensory and nutritional consequences of the reinforcing event. This fact should be kept in mind when we read the literature on "amount of reinforcement," for the majority of the studies indexed under this heading will have allowed two or more aspects of the situation to co-vary.

Although the term "amount" frequently is used in this loose fashion to refer to any of a number of manipulations of the reinforcer, the results of the many studies in this area seem more easily organized if we distinguish three classes of operations: (1) manipulations of the mass or volume of food, water, or other substance which is ingested by the subject; (2) procedures which cause variations in the amount of consummatory responding (that is, the number of licks, pecks, and so on); and (3) methods which employ differing concentrations of sucrose, saccharin, or other substances.[3] Intensity of positively reinforcing electrical brain stimulation seems to belong with the third category, for it produces functional relations like those found when concentration is varied. In contrast, intensity of aversive stimulation from which escape can occur seems to have behavioral effects analogous to the procedures in category 1 (see pp. 720–721).

Amount of Reinforcer and Amount of Consummatory Responding

Amount of reinforcer The reference experiments in most textbooks are those of Crespi (1942) and Zeaman (1949). Crespi changed the procedure of his experiment as it developed, making it a difficult one to summarize. For that reason, we will describe the method employed by Zeaman. In general, these two studies are prototypes of many that subsequently have been designed to explore specific features of the amount of reinforcement variable.

[2] "Consummatory activity" in studies of animal behavior typically refers to the last responses in a behavior sequence (that is, the behavior that consummates or completes that particular activity cycle), rather than to the responses involved in consuming (ingesting) solids or fluids. Frequently these two terms have identical meanings: The consumption of a food pellet consummates the response sequence that started with bar pressing. In other instances, the meanings of the terms are easily distinguished, as when sexual behavior is allowed as the reinforcing operation.

[3] It is not common usage to refer to the number of reinforced trials or reinforced responses as "amount of reinforcement."
Figure 15.1. Floor plan showing the essential features of a simple alley apparatus. All such devices include at least the following features: a start box in which the animal may be detained until the trial is to begin; a door through which access to the alley itself is gained; the alley, at the end of which is placed the goal box; a second door, to be closed behind the animal to prevent retracing; and devices for timing the performance. Two time indices have been taken in most cases: starting latency, timed from when the start box door opens until the animal leaves the start box; and time to traverse the major portion of the alley. In the earliest alleys, timing was done with stopwatches or by hand closure of switches. Later, depressable floor sections were used to control timing circuits. Today, most alleys use the interruption of a light beam falling on a light-sensitive device to determine when the animal reaches one of the criterion points. In the sketch above, the photocells are placed 5 feet apart, simplifying the conversion of alley time into speed (in feet per second). Speed measures are typically employed, for they can be more readily compared when different lengths of alley are employed, and because they are multiples of the reciprocals of time scores, they are less skewed and more easily adapted to the assumptions of standard statistical techniques than simple time measures. Synonyms that are used commonly are: straight alley, alleyway, or runway. Plastic or metal inserts may be placed in the goal box, start box, or alley to serve as discriminative stimuli. If more than one condition of reinforcement is to be employed, it sometimes is desirable to prevent the subject from seeing the reinforcer from the alley. In such cases, curtains sometimes are hung near the goal area, or the goal box is built in an L-shape, requiring the subject to make a 90-degree turn at the end of the run. In spite of the turn, this device continues to be classified as a straight alley.
Figure 15.2. Each group of rats was given one run per day in a short alley. The values plotted show the average time the animals needed to leave the start box when the door was raised. The amount of food found in the goal box is indicated by each curve. Two groups (.20 and 1.6) have been omitted for ease of inspection; they fell in their proper places in the distribution. (After Zeaman, 1949.)

Zeaman assigned rats to 7 groups and gave each animal 18 daily acquisition trials in a 3-foot runway. The groups received either 0.05, 0.2, 0.4, 0.6, 0.8, 1.6, or 2.4 g of cheese per trial. Latency of leaving the start box, and time required to run to the goal box were recorded. Both measures indicated that speed was a positive function of amount of food in the goal box.[4] The results for 4 of the 7 groups in this part of the experiment are summarized in Figure 15.2, and the main effect is quite clear: Larger amounts of food produce shorter starting latencies.

The group curves also seem to show relatively similar *rates* of improvement, as if the amount of food might be setting the asymptotic level for

[4] After eighteen days of training, some animals received a different amount of food. These results will be considered in the next section.

each group, with each trial contributing a constant proportion of the improvement needed to attain these "final" levels.[5] Indeed, it seems that almost any experiment in which simple measures of speed are made is likely to produce grossly similar results, whether the data are obtained using tasks that involve measures of reaction time, an alleyway, or simple motor skills (see Woodworth & Schlosberg, 1954, pp. 664–667): speed measures characteristically show less and less absolute improvement per trial as practice increases, with each trial eliminating a constant proportion of the distance remaining to the performance level at which behavior stabilizes. As a descriptive technique, this form of analysis seems to have some value quite apart from the role it was assigned in behavior theory. However, it is only with time-based measures that such treatments of the data are possible, and when we examine indices of performance based on the proportion of correct responses or the elimination of errors, the rate of approach to the final level of proficiency may sometimes show marked discontinuities, with sudden improvements in the scores of individual subjects. It is possible that these discontinuities reflect sudden changes in the way in which the subject perceives the situation (see the discussion of the continuity-noncontinuity problem, Chapter 17). However, it is equally possible that the apparent discontinuity may sometimes result only from an inability to score such responses any more finely than "correct" or "incorrect," whereas speed of response may be measured along a continuously variable dimension. If this is true, we might expect speed measures to be "more sensitive" than choice measures to manipulations of independent variables, in that changes in speed might be detected before changes in choice. This does seem to be the case in at least some tests involving discrimination (Hall, 1960; Terman & Kling, 1968).

Subsequent studies have confirmed the main outcome of the Crespi and the Zeaman experiments: with separate groups of subjects each receiving one condition of reinforcement, and with discrete-trial procedures,[6] large differences in the ratios of the amounts of reinforcers will produce differences in speed of response. However, it is well to note that many experimenters failed to find such effects even though they employed such differences in reinforcers. Such results have led to numerous attempts to separate experimentally the cluster of factors that is involved whenever amount of reinforcer is manipulated, and evaluating such factors as the length of time subjects are exposed to goal box stimuli, the number of responses involved in ingestion, and the amount of the substance itself that is ingested became one of the favorite research topics of the 1950s. Obviously, a complete separation of these factors is impossible in the intact animal, but some partial separations have been accomplished. For example, Fehrer (1956) studied three groups of water-deprived rats in a **U** maze. She allowed one group 40 seconds to drink in the goal box on each trial and another group 10 seconds to drink. The third group was also allowed to drink for 10 seconds, but then was held in the goal box for an additional 30 seconds. In this way, two durations of goal box time, and two durations of drinking time were compared. Even though there were very marked differences in amount of water drunk per trial using this procedure, there were no differences in speed of running or in choice behavior.

Of course, if the rat is held in an empty goal box, it might have some detrimental effect on the subject's behavior, but other procedures which eliminated this factor have produced results similar to those of Fehrer. For example, Kling (1956) used two sizes of drinking tubes, so that rats would be able to obtain water at high or low rates. Each of four groups was assigned to a different one of the four combinations of conditions produced by large and small drinking tubes, and long (120 seconds) and short (10 seconds) goal-box durations, thus allowing amount of fluid to be separated from the amount of time in the goal box. Despite the large differences in the conditions of reinforcement, equally rapid improvements in running speed, and equally fast terminal rates were found for all groups but the one trained with the short duration and

[5] Data such as these led Hull (1943, Chapter 9) to assume that reinforcers set upper limits to which "habits" might grow. This position soon was modified to give reinforcers "incentive motivation" characteristics (Hull, 1952).

[6] As contrasted with "free-operant" procedures, where the subject's responding is not divided into trial periods. See page 602.

small tube. Again, as in the experiment cited above (Fehrer, 1956), the results indicate that in designs where each group receives but one condition of reinforcement, even quite large differences in amount of reinforcer may have little differential influence on behavior unless several other aspects of the situation are allowed to vary concomitantly. Once this conclusion became apparent, further attempts to break down the influence of the various factors involved in reinforcement began to disappear from the research literature.

One persistent problem encountered in experiments in which alleyways and similar types of apparatus are used is the control of extraneous stimulation: A quiet room and a masking noise can be used to overcome auditory stimulation from outside the experiment, and conditions of illumination and appropriately placed screens can block off unwanted visual stimuli. However, the handling of the animal prior to each of the trials, and the uncontrollable variability in patterns of stimulation from trial to trial and place to place in the apparatus, combined with the fact that we can obtain only a small number of scores from each subject, typically result in relatively large variances in measures of responding. Such variability may conceal reliable differences in behavior attributable to variables such as the amount of reinforcer. Often the only remedy is to use the averaged results from large groups of animals. By comparison, free operant techniques usually are compatible with isolation of the subject, and thus can avoid some of these problems of uncontrolled variation in stimulation. Such controls, plus those afforded by repeated exposure of the organism to the same situation, can produce relatively stable rates of responding in individual organisms. Hence, one might expect that these procedures would be especially valuable in exploring the effects of amount of reinforcer.

Typically, experimenters using free operant techniques prefer to compare the effects of various treatments by applying each treatment to every organism, rather than using separate groups of subjects to evaluate each treatment condition (Sidman, 1960). As we shall see, exposing a subject to more than one condition of reinforcement immediately changes the nature of the problem, but there is still another problem introduced by the use of free operant techniques in this context. The main difficulty can be stated quite simply: The rate of response is very strongly influenced by the reinforcement *schedule,* and it is influenced relatively little by the reinforcing condition itself. It is well known that response rate is conditionable (see, for example, Morse, 1966, especially pp. 73 ff. and 92 ff.), and therefore the more we strive to achieve stability of behavior, the more unlikely it becomes that manipulations of the amount of reinforcer will have significant effects on response rate. This domination of response rate by the schedule of reinforcement seems relatively weak during the early moments of a session or immediately following changes of conditions within a session; comparisons of the effects of providing different amounts of reinforcer on the subject's behavior at these times produce the expected positive correlations of response rate and amount of reinforcer (Keesey & Kling, 1961). In addition, the use of fairly short sessions (such as 15 or 20 min) also allows some of the inflexibility of schedule-determined response rates to be avoided.

Still other possibilities for the independent manipulation of components of the reinforcing situation exist when surgical rearrangement of the organism is employed. For example, if a rat's esophagus is severed, and if the cut end of the upper esophagus is sutured to the skin of the chest, everything he may later drink will emerge from this esophogeal fistula ("sham drinking"). Then, if one end of a tube is passed through the severed end of the lower esophagus and into the stomach while the other end of the tube is brought under the skin to the top of the head and fastened there securely, solutions may be sent into the stomach without making any contact with the mouth or requiring any con-

summatory responding by the animal (Mook, 1963).[7] For psychologists, one of the most interesting questions to be answered by such techniques is whether or not stimulation of the mouth or changes in the gut can have reinforcing effects when they are divorced from one another. They do, at least in animals that have a past history of normal eating experiences (see, for example, Miller & Kessen, 1952).

How do conditions of reinforcement (such as the amount of food given the subjects) influence behavior? In our own case, we might assume that we recall the reinforcement conditions of past sessions, and then consciously and rationally tune our efforts to the predicted payoffs. Most psychologists have been reluctant to assume that nonhuman organisms are endowed with similar capacities, at least until simpler hypotheses have been shown to be insufficient. One of the more frequently adopted viewpoints flows logically from the Watsonian brand of behaviorism (Watson, 1930), which conceived of all psychological processes in terms of muscular or glandular responses and their associated stimuli. To extend this reasoning to a nonverbal organism who shows "anticipation of" reinforcement conditions, we might assume that at least some components of the eating responses can occur in the absence of food itself, and that these components can become conditioned to (previously neutral) stimuli that are present in the goal box or are emanating from the feeding device. It is also reasonable to assume that, through stimulus generalization, stimuli similar to those of the goal box can evoke the conditioned components of the eating responses. These conditioned responses have been called "fractional anticipatory goal responses" (Spence, 1956). Of course, eating a larger amount of food allows more opportunities for these responses to become conditioned. Hence, animals reinforced with larger amounts of food should show these fractional anticipatory goal responses earlier in training, and with greater reliability, than would animals reinforced with smaller amounts of food.

Although such hypothesized responding was, in the beginning (for example, Hull, 1932), purely a theoretical device, we now know that "anticipatory" responses of this type do indeed occur, and that they do play a role in determining choice behavior and response speed. For example, Miller (1935) found that the use of distinctive goal responses would produce overtly recognizable anticipatory goal responses while the animals were running in a straight alley. Rats were given daily opportunities to eat while in one compartment and drink while in another. The food compartment was so constructed that the food cup could be reached only if the rat climbed up a step and twisted his head to the right; the water compartment was fashioned so that it could be reached only if the rat twisted his head to the left. Half the animals received daily alleyway trials with food in the goal box, and the other half ran to water. In the alley itself, the animals ran holding their heads in the position appropriate to the reinforcer they were to receive, and the "anticipatory" positioning became more noticeable as the animal approached the goal box. Thus, components of the distinctive response patterns previously associated with eating or drinking occurred prior to contact with the reinforcers themselves.

The frequency, and possibly the vigor, with which such anticipatory responses occur increases as the goal area is approached. This phenomenon has been illustrated by use of a preparation of the type developed by Patten (Patten & Rudy, 1967). Under general anesthesia, a few small screws are threaded into the skull of a rat, and a stainless steel tube is anchored to the skull in a small platform of dental cement. Alternatively, the tube can be held in place with a small harness. The tube is curved over the end of the snout, so that the rat can lap from it merely by extend-

[7] Other varieties of operation to separate mouth and stomach have been employed for somewhat similar purposes by Miller and Kessen (1952) and by Epstein and Teitelbaum (1962).

ing his tongue a few millimeters beyond his lips. The other end of the metal tube (near the rat's ears) is connected to a piece of flexible tubing, which in turn connects to a source of fluid. Each touch of the tongue against the tube can be sensed and recorded by a "drinkometer" circuit (Stellar & Hill, 1952); the fluid can be held within the tube (in which case the lap is "anticipatory"), or drops can be allowed to escape when the rat laps, thus reinforcing the tongue movements. Even if such reinforcement is given only when the rat reaches the goal area, the anticipatory responses soon develop, and they occur more frequently the closer the animal approaches the goal.

The functional significance ascribed to such anticipatory responses by theorists falls, for the most part, into two classes. For convenience, these may be labeled "motivational" and "associational." As illustrations of the motivational interpretations, we may mention the following assumptions: that the occurrence of anticipatory responses in the absence of the wherewithal to consummate the striving is innately exciting (Sheffield, 1966); that anticipatory responses and non-reinforcement produce frustration responses, which in turn can have a variety of behavioral consequences (Amsel, 1967); or that anticipatory responses and the stimuli they generate are the immediate determinants of incentive motivation (Spence, 1956). The general theme of motivational interpretations is that anticipatory responses in one way or another cause an increase in the vigor or rate of whatever instrumental responses are prepotent in the situation.

An associational interpretation, on the other hand, would ascribe to anticipatory responses a direct involvement in what the organism learns about the situation. In an indirect manner, Hull's (1952) assumption that the stimuli generated by anticipatory responses are secondary reinforcers (because they are similar to the stimuli generated by the consummatory responses themselves) might be considered a peripheral variety of associational viewpoint, since the secondary reinforcers determine in part what is learned. But a more directly associational viewpoint would emphasize the discriminative stimulus role of the stimuli resulting from anticipatory responses. This was the use made of such hypothetical responses by Hull in his descriptions of the manner in which a stimulus-response psychology could account for anticipation of events (for example, Hull, 1930), and Capaldi (1967) recently has revived interest in this point of view. Seen in this light, any alteration in anticipatory stimuli would have the same effects as all other alterations in discriminative stimuli: errors would increase, speed would decrease, and so forth.

Until fairly recently, "anticipatory responses" ordinarily meant the responses which the theorist assumed to be present. Within the last few years, however, there have been developed several techniques which allow the direct observation of responses which seem to have the properties attributed to fractional anticipatory goal responses by Spence (1956) and others. The measurement of anticipatory lapping has already been mentioned (p. 621). The concurrent observation of classically conditioned salivation and instrumental responses reinforced with food (see, for example, Shapiro & Miller, 1965; Williams, 1965) provides another means of investigating the interactions of reinforcers, instrumental responses, and the anticipatory responses which presumably determine incentive and secondary reinforcement. With such tools, an accelerated program of research involving anticipatory responses may be anticipated in the next few years.

Amount of consummatory responding Because the amount of behavior involved in obtaining and ingesting foods and fluids ordinarily is perfectly correlated with the amount of the substance, the logical possibility exists that it is the *behavior* of food-getting, rather than the stimulus properties or the metabolic characteristics of the food, that determines reinforcement value. Unfor-

tunately, there seems to be no way to test this hypothesis directly, for even if we employ sham feeding (during which all the food emerges from an esophageal fistula instead of continuing on to the stomach), we still have left the taste and smell of the food which is confounded with the seizing, chewing, and swallowing. Therefore, experimenters have been forced to employ indirect tests of the "consummatory response" hypothesis. Several schemes have been employed, all of which are variations of the basic procedure developed by Wolfe and Kaplon (1941): They gave their chicks a unit of food in one piece or as four quarter pieces; Kling (1956) presented fluids through large or small diameter drinking tubes; Hulse (1960) pumped large or small drops to the end of a drinking tube; and Hall and Kling (1960) distributed a given volume of fluid into two or into six drinking cups. In all cases, a partial separation is obtained of the amount of consummatory behavior and the amount of substance received; and in all cases, the conclusion reached is the same: increasing the amount of consummatory responding will increase slightly the reinforcing properties of the substances. The effect is small, but it is present with such consistency that we dare not ignore the behaviors emitted during reinforcement when evaluating the efficacy of various reinforcers.

A response-probability theory of reinforcement If consummatory responding contributes to the overall effectiveness of reinforcers, perhaps responding itself has reinforcing properties. Premack (for example, 1965) has proposed just such a theory, making the specific assumption that any response may serve as the reinforcer for any other response that has a lower probability of occurrence. This proposition requires some revision of typical modes of thinking about reinforcers. According to Premack's theory, a reinforcer is not an event but a response. More specifically, *reinforcement* is a relation between a response that is being reinforced and a response that is reinforcing, with the more-probable response being the reinforcer for the less-probable response. Furthermore, Premack (1965) has suggested that this relational view might also be extended to the problem of why some stimuli function as unconditioned stimuli in the Pavlovian situation, while others do not have this property: Conditioned stimuli usually elicit responses which are weak and, in comparison with the typical unconditioned response, less probable of occurrence, hence the reflex associated with presentation of the unconditioned stimulus can reinforce the reflex associated with the conditioned stimulus, but not vice versa.

How is the probability of responses to be determined? Premack asserts that the probability may be estimated from response durations, and in addition, that the reinforcement relation is independent of the means by which the durations are manipulated: if one can make Response A more probable than Response B, then A will serve as a reinforcer for B. Furthermore, if there is some way to increase the probability of B to where it exceeds A, then the relation can be reversed, and B will become the reinforcer. Several ingenious experiments supporting the theory have been published. For example, monkeys were given the opportunity to manipulate several kinds of gadgets (a lever, a door, and a plunger, among others), and the base level at which each animal manipulated each device was determined. Then, the devices were presented in pairs, but one was locked against movement and the other was left free to be moved. Whenever the unlocked device was operated, the locked device was unlocked and stayed unlocked until the monkey manipulated it, at which time it again was locked. Thus the opportunity to manipulate one device depended on the manipulation of the other. All possible pairs of devices were presented, and in each case where one of the animals had shown a preference for manipulating one of the devices in a pair beforehand, the hypothesis was supported: high-probability responses reinforced low-

probability responses, but the reverse was not the case.

Further experiments have shown that drinking and running can be used either as the reinforced or reinforcing activity, depending on their relative probabilities as manipulated by depriving animals of water or activity (Premack, 1962); also playing a game can reinforce candy eating, or vice versa, depending on which activity occurred with the greater probability in a given child (Premack, 1959).

Clearly, a critical problem for adequate evaluation of this theory of reinforcement is the specification of probabilities of responses. In most cases, Premack suggests that comparisons of the duration of each response is likely to be a better index than the rates at which the responses occur. For example, a child may be observed to spend 10 minutes finger painting, but only 10 seconds speaking with others in the room, and yet his rate of emitting words during the time he is speaking might be many times higher than the rate with which he swings his paint-dabbed fingers at the paper. Using the durations to estimate probabilities, the prediction in this case would be that withholding the opportunity to paint until the child has spoken would increase duration of speaking.

Although Premack's theory is a provocative one, it has as yet stimulated but a small amount of research, some of which seems to call into question the generality of the basic hypothesis. For example, Eisenberger, Karpman, and Trattner (1967) used high school and college students in a series of experiments in which the freedom to make one response (such as turning a wheel) was contingent upon their making another response (such as pressing a bar). The results conformed to Premack's predictions only when the response to be reinforced was of low probability to start with; if it was of moderate to high probability, it could not be increased, even though there was considerable room for further improvement. (Indeed, suppression of high frequency responses was observed in many cases.) Other observations suggested that the key feature of the contingency-reinforcement relation might be the suppression of a response below its free-running rate when it is paired with another response, and that the increase in rate attributed to reinforcement might merely be a recovery from this suppression and a return toward the former, unpaired rate. Premack (1965) had observed such suppression when responses were paired, but Eisenberger et al. suggest that this is not only a result of the paired testing, but the "necessary and sufficient condition for reinforcement in the contingency situation . . ." [p. 350].

Other criticisms of the response-probability theory have been discussed by Leeper (1965), but at the least, Premack's hypothesis has already had the extremely valuable effect of suggesting a fresh way in which to view a broad variety of problems related to reinforcement and motivation.

Effects of Varying the Concentration of Solution Used as a Reinforcer

As we have noted, in the typical animal experiment, amount of reinforcement could not be considered a unitary dimension. When the weight or number of pieces of food are varied, several potentially important variables are confounded. Guttman (1953) suggested that use of liquid food, such as solutions of sucrose (common table sugar) as reinforcers, offered the opportunity for greater control over the reinforcer than did the use of solid food. Amount of reinforcement could be studied by varying the concentration of the solution without concomitantly varying stimulation (visual, olfactory, tactual) prior to ingestion and without introducing possible differences in required consummatory activity.

Guttman proceeded to study the effects of varying the concentration of sucrose solution used as the reinforcer on response rates of rats in a bar-press apparatus. The sugar solutions were delivered to the rats by means of a small (.005 ml) dipper cup which was
Figure 15.3. Mean rate of bar pressing by rats as a function of the concentration of sucrose solution used as the reinforcer with a continuous reinforcement schedule in effect. The concentrations are plotted on a logarithmic scale. Each point on the curve represents a different group of animals. The data are from the second day of bar-press training during which each animal was given 250 reinforcements. (After Guttman, 1953.)
Figure 15.4. Mean rate of bar pressing by rats as a function of the concentration of sucrose solution used as the reinforcer with a variable-interval 1-minute schedule of reinforcement in effect. The concentrations are plotted on a logarithmic scale. Each point on the curve represents a different group of animals. The data are from 5 successive daily half-hour experimental sessions. These animals had also been used in an earlier phase of the experiment, concerned with continuous reinforcement, the results of which are shown in Figure 15.3. (After Guttman, 1953.)

operated by a motor. The rats were divided into four groups, each group differing in the concentration of sucrose solution. Concentrations were 4, 8, 16, and 32 percent by weight.[8] In the first part of his study, each bar press was reinforced (continuous reinforcement or CRF schedule). The relationship between the rate of bar pressing and concentration of sucrose, which we will refer to as the rate-concentration function, was nonmonotonic (Figure 15.3). Rate of bar pressing increased with increases in concentration to 16 percent, but then declined with the further increase to 32 percent. In a second phase of the study with the same groups, all conditions were the same, except that a fixed-interval (FI) 1-minute reinforcement schedule replaced the CRF schedule, so that only the first bar press after each one-minute interval was reinforced. The rate-concentration function was no longer nonmonotonic. Bar pressing increased roughly linearly as a function of the log concentration of sucrose solution (Figure 15.4). The concentration of the sucrose solution was clearly

[8]Because confusion might arise from attaching differing meanings to the terms used to describe the concentration of solute in solution, recommendations regarding preparation of solutions were published by Pfaffmann and his colleagues (1954). Percentage concentration by weight refers to the weight of solute divided by weight of solute plus weight of solvent. By this method a 50 percent solution of sucrose would be prepared by adding 10 g of sucrose to 10 g of water, preferably distilled water.

shown to be an important variable, but the exact shape of the rate-concentration function varied with the reinforcement schedule. The reason for this was not entirely clear at the time, although Guttman discussed several hypotheses.
Figure 15.5. Mean rate of bar pressing by rhesus monkeys (*Macaca mulatta*) during successive 5-minute periods within daily experimental sessions. The different curves in each graph are for the different concentrations of sucrose solutions used as reinforcers. The upper graph is for experimental sessions during which the schedule of reinforcement was a variable-interval (VI) 30-seconds and the lower graph is for those during which the schedule was continuous reinforcement (CRF). The VI data are for 6 animals and the CRF for the same 6 plus an additional animal. Note that with the VI schedule the curves are all nearly parallel to one another, whereas with the CRF schedule the curves for the 2 highest concentrations decline considerably more rapidly within sessions than do those for the lower concentrations. (After Schrier, 1965.)

A series of studies by Collier and his coworkers (Collier & Siskel, 1959; Collier & Myers, 1961; Collier & Willis, 1961; Collier, 1962) using rats has done much to clarify matters regarding the factors influencing the form of the rate-concentration function. Similar results have been obtained in studies with monkeys (Schrier, 1965); thus the conclusions apparently can be applied to the behavior of different species. The following picture emerges from these studies: If we look at the results early enough in a session, the response rate will be found to be an increasing function of the concentration of the reinforcer. Specifically, the *initial* response rate may be regarded as an increasing, roughly linear, function of the log of the concentration of the reinforcing solution. Over the course of a session, the response rate declines. As illustrated in Figure 15.5, the rate of this decline is greatest at high concentrations when the volume per reinforcement is large or the density of reinforcement is high (that is, when the time between reinforcements is short, as it is on a CRF schedule, or on a short FI or VI schedule as compared with a long FI or VI schedule). The result of this relatively greater decline at higher concentrations is the nonmonotonic rate-concentration function of the type seen in Figure 15.3. The larger the volume and the higher the density of reinforcement, the lower the concentration at which the peak rate occurs and the earlier in the session the nonmonotonicity is observed.

Results such as those described above suggest that at least two classes of events control the momentary response rate of subjects (McCleary, 1953; Hulse, Snyder, & Bacon, 1960; Collier & Myers, 1961; Schrier, 1965). One of these classes includes the various sensory events (olfactory, gustatory, tactual) accompanying ingestion. The response rate is an increasing function of the intensity of these events. The second class of events is the momentary or immediate post-ingestive load, or what might be called "momentary satiation," with response rate a decreasing function of this load. The adjectives "momentary" and "immediate" distinguish this class of

events from variations in the nutritive state of the animal or its metabolic activity, for the changes in response rates within sessions seem to occur well before assimilation of the ingested solutions could be an important factor. The first class of events is most important in control of the initial rate of response, while declines in responding within sessions are primarily attributable to the second class of events—at least when conditions of high density of reinforcement, high concentration, and large volume are combined.

Mook (1963) has recently reached somewhat similar conclusions about the interacting roles of the mouth and postingestive factors on the basis of measures of intake of sucrose and other solutions by rats. By means of surgical procedures, rats were prepared with esophageal fistulas, so that any fluid swallowed emerged from an opening in the throat (sham drinking, p. 620), and with cannulas through which solutions could be injected into the stomach as the animal drank. Thus, Mook was able to compare the intake of different concentrations of solution under conditions of sham drinking and sham drinking combined with a stomach input of the same or different solutions. His results agreed with the conclusions drawn above except for a nonmonotonic intake-concentration function found when sucrose drinking was accompanied by nothing entering the stomach. According to the above-mentioned hypothesis, we would expect under these circumstances to find an increasing, monotonic function. Mook suggests that this nonmonotonic function may reflect sensory adaptation, brought into play as a result of the greater total intake under this condition than when the fluid being drunk was allowed to enter the stomach. Undoubtedly sensory adaptation should be considered as a possible factor influencing responding in operant studies of the type considered in this section, at least when large volumes of highly concentrated solutions are delivered at a high frequency.

One interpretation of the data that have been discussed so far in this section is that the reinforcing effects of a sucrose solution are always directly related to its concentration, or to whatever parameter or parameters determine the intensity of the sensory consequences. The immediate and long term postingestive factors, among others, are superimposed on the sensory factors, concealing the true reinforcement function. As Guttman (1953, p. 222) has put it, ". . . the reinforcing agent . . . can be explicitly treated as a *stimulus* and its properties and functions so described." This in turn suggests that the procedures and results of psychophysics should be directly applicable to the study of reinforcement.

Although a number of sensory modalities are involved during ingestion of a food reinforcer, we would guess, of course, that taste would be one of the most important. Furthermore, at least in the case of the sugars, we might further speculate that the reinforcing effects are directly related to the sweetness of the solution. One bit of evidence which supports this notion was obtained by Guttman (1954), in the same bar-pressing apparatus used in his earlier study. When humans are given equal concentrations of the sugars, sucrose and glucose, sucrose is uniformly judged to be sweeter. Guttman used varying concentrations of glucose and sucrose for reinforcement of bar pressing by rats. He found, throughout the range of concentrations used, that at equal concentrations, sucrose was indeed more reinforcing than glucose, as judged by rate of bar pressing.

Saccharin is a chemical that has interested psychologists for a number of years because it tastes sweet but is non-nutritive. Seventy-five to 90 percent of ingested saccharin is eliminated within the first 24 hours in urine and the remainder in the feces. Rats prefer saccharin solutions to water, as determined by two-bottle tests (Richter, 1939), which tempts us to infer that saccharin solutions taste sweet to these animals also. We would expect, therefore, to find that saccharin is also reinforcing. This has been shown to be the case for rats in a T maze (Hughes, 1957) and in experiments involving bar pressing (Cockrell, 1952; Collier, 1962). In the latter studies,

various parameters of the rate-concentration function discussed above were found to operate in the same way for saccharin as for sucrose. Not all species of animals react to saccharin in this way. Squirrel monkeys (*Saimiri sciureus*), for example, show no preference for saccharin solutions when offered a choice of such solutions and water. However, they do prefer another nonnutritive sweetener, dulcin, to water, and dulcin has been found to reinforce bar pressing by these animals (Fisher, Pfaffmann, & Brown, 1965). Although it has not been tried, it would be extremely surprising if saccharin were found to reinforce bar pressing in these animals under circumstances similar to those in which sucrose and dulcin do.

The relationship between preference and reinforcement suggests that the reinforcement value of a substance is related to its taste and perhaps other sensory qualities. But can it be concluded that a good taste is all that a substance needs to be a reinforcer? This deceptively easy question proves to be impossible to answer with any precision. Suppose we define "tasting good" in terms of preference, so that whichever of two substances is selected is the one which "tastes better" than the other. We could compare, for example, sucrose and saccharin at various concentrations, and then state what concentration of the one is preferred over which concentrations of the other, or which concentrations of each are "equally preferred." Such comparisons have been made for rat (see, for example, Young & Madsen, 1963) and for man (see, for example, Lemberger, 1908, as cited by Pfaffmann, 1951), but for comparisons of the preference data with reinforcement values, we shall have to restrict our attention to the rat.

Figure 15.6. Equal-preference function for solutions of sucrose and saccharin. The graph shows the mean concentrations of sucrose (ordinate) that were preferred equally as much as various concentrations of saccharin (abscissa). Concentrations are specified in g/100 ml of solution. Each mean is based on the preference scores of 8 animals, except those for the 2 highest concentrations of saccharin (0.63 and 1.00), which are based on scores of 7 animals. The vertical lines indicate the range of concentrations of sucrose that were equally preferred by individual animals to each concentration of saccharin. The variability was greatest at the highest concentration of saccharin. (Young & Madsen, 1963.)

The average "equal preference" curve obtained by Young and Madsen is shown in Figure 15.6. Note that the most concentrated sucrose solution used was 4 g per 100 ml, or approximately a 4 percent solution; that it was matched by a saccharin solution of approximately 0.4 percent; and that no saccharin solution of any concentration could be found which was preferred to the stronger sucrose solutions. Moreover, as saccharin concentrations were increased beyond 0.4 to 0.6 percent, preference fell, as indicated by the drop in the equal preference curve.

If reinforcement value, as indicated by bar press rates, were determined only by taste preference, we should predict from the "hedonic equivalence function" that the same response rates would be obtained when using either a 3 percent sucrose solution or a 0.4 percent saccharin solution, and that equal response rates would be supported by 0.05 and 1.0 percent saccharin solutions. Unfortunately, no experiment has investigated sucrose and saccharin preferences and reinforcement values under exactly equivalent conditions, so we are forced to compare

TABLE 15.1 SOME EQUIVALENT CONCENTRATION VALUES FOR AQUEOUS SUCROSE SOLUTIONS FREQUENTLY USED IN BEHAVIORAL EXPERIMENTS.[a]

Percent by weight	*Molar concentration*	*Percent by weight*	*Molar concentration*
1	.029	25	.809
2	.059	30	.988
4	.118	30.3	1.0
5	.149	32	1.063
8	.241	40	1.375
10	.303	43.2	1.5
15	.464	50	1.796
16	.497	54.4	2.0
20	.632	64	2.443

[a]Most of these values are from Table 63, pages D 163–164, *Handbook of Chemistry and Physics*, 46th Ed., Cleveland: Chemical Rubber Co., 1965–1966. The other values were determined empirically.

TABLE 15.2 COMPARISON OF RESPONSE RATES WITH DIFFERENT CONCENTRATIONS OF SACCHARIN AND SUCROSE SOLUTIONS USED AS REINFORCERS.[a]

Saccharin		*Sucrose*	
Approximate percent concentration	*Approximate responses per minute*	*Approximate percent concentration*	*Approximate responses per minute*
0.075	3.2	4.0	4.5
0.45	5.0	8.0	5.25
1.02	5.8	16.0	6.5
1.52	5.4	32.0	7.8

[a]The saccharin data are from Cockrell (1952), Experiment II, Procedure 10b. The sucrose data are from Guttman (1953), PR, each animal as its own control. Response rates have been estimated from published figures.

across experiments and conditions.[9] However, some portions of the experiments of Guttman (1953) and Cockrell (1952) employed quite similar procedures, and we shall therefore hazard a comparison of their findings. Table 15.2 presents the approximate mean response rates obtained by these investigators using a 1-min fixed interval reinforcement schedule, with every animal exposed to every solution on each day. If we interpolate with abandon, we can guess that the response rate that might have been obtained had Cockrell used a saccharin solution of 0.3 percent might have been quite similar to the rate Guttman might have obtained had he used a 3 percent sucrose solution. However, it is only at this low end of the dynamic range for each solution that any successful predictions of response rates from preference data can be made; all other predictions of rate from preference seem to be wrong. For example, the response rates would suggest that 8 percent sucrose should be about equally preferred to 0.5 percent saccharin, but this is not true: above 4 to 5 percent sucrose, no saccharin solution is ever preferred as much. Similarly, the preference data would suggest that 0.05 and 1.0 percent saccharin solutions would produce approximately equal response rates, but Cockrell's results with the 0.075 percent solution indicate that the response rate would be very low with a 0.05 percent solution, and near its peak with a 1.0 percent solution.

The data compiled by Young and Madsen are based on very brief exposures of the solutions to the rats, which is similar to the exposure to solutions provided by the small

[9]In reading the literature, we frequently are impeded by the need to translate from one mode of specification of concentration to the other. The majority of studies have used either percent concentration by weight or molar concentration. Some typical sets of relations between these are presented in Table 15.1.

amounts of substance carried on the dippers. Preference data based on long-term exposures to saccharin and sucrose (for example, Collier & Novell [1967] and Hammer [1967]), however, seem to lead to similar conclusions: Except in the range below 4 percent sucrose, no saccharin solution will ever be preferred to a sucrose solution.

In summary, we might conclude that the taste quality of substances, as evaluated from equal-preference data, offers only a poor basis for predicting reinforcement values, as reflected in response rates. Of course, we must remind ourselves that, in comparing saccharin and sucrose, we are dealing with solutions that are similar only in that each tastes sweet to man. As do other sweet substances, each has its characteristic flavor, and saccharin also has a marked bitter component (for man) which we begin to detect in concentrations greater than 0.5 percent. Probably only when we compare substances which are almost indistinguishable (as sucrose and glucose, at all but the highest concentrations) will "equal sweetness" or equal preference offer a sound basis for prediction of equal reinforcement values, and even then we should not expect perfect correlations between measures of preference and measures of reinforcing effects.

A Word of Caution

It is difficult to view the studies we describe above with complete objectivity, for we have many preconceptions about the way in which reinforcer variables should influence behavior based on our common-sense notions of how to win friends and influence people and our impressions of the influence that evolutionary pressures should have had on the development of the higher organisms. It therefore comes as something of a shock to some students of behavior when they discover that amount of reinforcer frequently is quite an ineffective variable when manipulated in laboratory studies, and that there is considerable discrepancy between the results of studies which appear to be equally well designed and executed.

At least some of the differences between studies must stem from our tendency to place into a single category some experiments which might better be considered independently. For example, we have discussed as separate problems the manipulation of the amount of food and concentration of sucrose (and other) solutions. Originally (see p. 624), the use of sucrose solutions was thought to provide a superior technique for investigating the amount of reinforcer, but it now seems that manipulation of amount (weight, volume, and so on) may have behavioral effects which are distinct from those resulting from manipulation of taste and other factors correlated with changes in concentration. One reason for thinking that there may be differences between amount and concentration effects stems from the relative potency of these factors in behavioral situations: When both volume and taste factors are manipulated in the same experiment, the total effect attributable to amount always seems to be smaller than that attributable to taste (see Hutt, 1954; Collier, 1962; Schrier, 1965). This effect is seen in striking fashion when experimenters have manipulated volume without a confounding change in ingestion time, as in studies where the size of individual drops coming from the drinking spout can be controlled (Berkley, 1963).

A further source of discrepancies among studies is the failure to take into account the pretraining procedures when we compare the results of experiments. Consider an experimental design in which several reinforcement conditions are to be evaluated, perhaps by using the rate of bar pressing as the dependent variable. One experimenter assigns subjects at random to each experimental condition, gives each of them the necessary magazine and bar training, and then runs the critical sessions (see, for example, Guttman, 1953). Another experimenter gives all his animals magazine and bar training with a single reinforcement condition, and then constructs matched groups of subjects based on the behavior observed during pretraining; each of these matched groups is then exposed to one

of the reinforcement conditions in which the experimenter is interested (see, for example, Hutt, 1954). The relative efficiency and power of these two designs may be argued on statistical grounds, but from the point of view of the behavioral effects there can be no doubt that they produce differences: When pretraining and training are carried out using different reinforcement conditions, a "shift" procedure exists, and the effects of differences in the amount and quality of reinforcer are enhanced (see pages 631-640 for a discussion of types of shift procedures and typical results). These and other procedural differences sometimes have been overlooked in attempts to summarize the literature on this area of study and account for at least a portion of the discrepancies among the studies.

SHIFTS IN AMOUNT OF REINFORCER

Constant-Reinforcer versus Variable-Reinforcer Methods

We describe here studies which are concerned with the general question of whether the effects of a particular reinforcer on behavior can be influenced by other reinforcers presented in the same or similar situations. The term that we shall use to indicate that one reinforcer is having an effect on another is "reinforcement-context effect." "Context" is used here in much the same sense as it is used in psychophysics (see pages 58-59) when talking about effects of the stimulus context or series.

Although a variety of methods have been used to study reinforcement context, most of them have involved a comparison of outcomes using two procedures—the "variable-reinforcer" and the "constant-reinforcer." "Variable-reinforcer" refers to any procedure in which the subjects are presented with more than one amount of reinforcer. In practice, this has been accomplished by giving each animal either a *single shift* from one amount to another or *repeated shifts* among amounts of a given set. "Constant-reinforcer" refers to the procedure of training separate groups of animals, each with a different amount of reinforcer throughout training, so that each animal is presented only one amount. We discuss separately the results of studies which have employed the single-shift type of variable reinforcer procedure and those which have employed the repeated-shift type.

Single Shifts in the Reinforcer

The reference studies on the question of shifts in the reinforcer were the ones carried out on rats by Crespi (1942) and Zeaman (1949), the preshift results of which have been discussed on pages 617-619. Both investigators, it will be recalled, measured performance of rats in a runway apparatus. The animals were given one trial a day. In the Zeaman experiment, after one group of animals was given a large amount of reinforcer (2.4 g of cheese) and another group a small amount (0.05 g) for 18 consecutive days, the amounts were reversed. On Day 19 and for the remaining 8 days of the experiment, the animals that had received the large amount of reinforcer received the small, and the animals that had received the small amount received the large. Zeaman assumed that the animals had
Figure 15.7. Idealized results of shifts in the amount of reinforcer. The curves represent the performance of 2 groups as a function of practice. During the preshift phase, one group was given a relatively large amount of reinforcer on each trial and the other a relatively small amount. During the postshift phase, the amounts given the 2 groups were reversed. The letters refer to regions of the graph that are discussed in the text.

reached the performance asymptote before the shifts were introduced. Though somewhat less straightforward in its experimental design and execution, the Crespi experiment had the same basic plan. Figure 15.7 represents the results as they were conceived by Crespi, Zeaman, and many subsequent writers. The four important regions of the graph are indicated by capital letters. Region A is there to remind us that the performance of the animals was supposed to have been asymptotic prior to the shifts in the amount of reinforcer. Region B shows that, as expected, the average performance level of those animals which were given an upward shift in amount of reinforcer increased, and the average performance level of those given a downward shift decreased. However, Crespi and Zeaman also noted two results that had not been expected. First, as can also be seen in Region B, the changes in performance occurred rapidly, with most of the increase or decrease taking place within the first three days following the shifts in amount. Second, as can be seen in Region C, the performance levels either overshot or undershot the control levels. The performance of the group which received the upward shift in amount of reinforcer increased to a level above that expected of the original large-reinforcer group had the reinforcer shift not occurred. Crespi called this overshooting of the control level by an upward-shifted group an "elation effect", while Zeaman referred to it as a "positive-contrast effect." Similarly, the performance of the group that had gotten a decrease in amount of reinforcer decreased to a level below that expected of the group originally given the small amount had it not received the reinforcer shift. This undershooting was called a "depression effect" by Crespi and a "negative-contrast effect" by Zeaman. Crespi's terminology reflected his belief that the contrast effects were emotional phenomena produced by the "unexpected" rewards. This conception of the nature of the contrast effects led Crespi to predict that they would be temporary in nature (Region D), though there was no clear-cut evidence for this in his own data.

Contrast effects, then, represent one type of reinforcement-context effect. Although the discussion to follow deals primarily with contrast effects, other types of reinforcement-context effects are also possible, as we shall see.

On the basis of the Crespi and Zeaman studies the concept of reinforcement-contrast effects was generally accepted and widely quoted by psychologists. Spence (1956), however, questioned whether Crespi and Zeaman had adequately demonstrated a positive-contrast effect. Both Zeaman and Crespi had used the performance of the large-amount group on the few days immediately preceding the shifts as the control level by which to judge the overshooting effect. As we indicate above, these investigators assumed that the performance levels of the animals had reached the asymptote by this time, and thus would not have shown any further change with continued training. Spence claimed that asymptotic performance levels are not reached in straight runway situations until after considerably more training than had been given by Crespi and Zeaman. The preshift "control" levels, then, merely represented a stage of practice at which performance had not reached stable levels. It should be emphasized that Spence's criticism applies only to Crespi and Zeaman's procedures for demonstrating positive contrast; dependence upon extrapolation from nonasymptotic performance for control levels would, in their case, work against a demonstration of negative contrast. Thus, if anything, the magnitude of the negative contrast effect found by Crespi and Zeaman would be expected to be greater if adequate controls were used. (Besides, in one phase concerned with downward shifts, Crespi did run a nonshifted control group during the postshift period.) Spence carried out a study on rats which was of the same general design as the previous ones except that the small-reinforcer and large-reinforcer animals were each given forty-eight daily trials before the amounts were changed. During the preshift training period, the performance of both groups, as

measured in terms of running speed, continued to rise well past the point at which Zeaman (but not Crespi[10]) had shifted the amount of reinforcer. As for the postshift period, Spence observed the rapid changes in performance that Crespi and Zeaman had noted and also the negative contrast effect. There was, however, no positive contrast effect. Indeed, the performance of the upward-shifted group remained somewhat below that of the control level.

Spence's critique and experiment, then, raised serious doubts about the existence of a positive contrast effect. This was of considerable importance because it was really the positive contrast effect that created a new problem for behavior theory. The negative effect was relatively easily dealt with in terms of standard concepts used in experimental psychology of learning (such as generalization decrement or frustration[11]), but the positive effect was not so easily dealt with.

Before going further, we might question whether the conditions in Spence's studies were favorable to the appearance of the positive contrast effect. The large reinforcer weighed 1 g (quite a large amount for rats). Also, the animals were deprived of food for 22 hours before each trial and had prolonged training. Thus, by the time the amount of reinforcer was shifted, the group that originally was given the large amount might well have been running at speeds close to the maximum that might be expected under the most favorable conditions of reinforcement, drive, and practice (the so-called "ceiling effect"). If this were true, we would not consider the chances of an upward-shifted group exceeding the speed of the control group to be very great. Also, even after the subjects have been given prolonged training, it does not seem advisable to rely on extrapolation as a means of obtaining control performance under any but the most rigidly controlled and specified conditions, something which is rarely the case in behavioral studies. In any event, a better way to test for contrast would seem to be to carry out an experiment in much the same way as did Crespi and Zeaman, except that only half the animals in each group should be given the upward or downward shifts in amount of food; the remaining half of each group would continue to receive the original amount of reinforcer and would constitute the control groups. Surprisingly, most of the subsequent studies concerned with demonstrating positive reinforcement contrast in the runway performance of rats have not fulfilled this simple design requirement and, hence, are subject to the same criticisms as the earlier studies. In one case (Di Lollo, 1964), subjects were given prolonged training before the upward shifts in amount of reinforcer, raising the possibility of a ceiling effect; in another (Ehrenfreund & Badia, 1962), no control group was used, and the shifts were introduced before the performance levels had reached the asymptote. However, in a recent study (Schrier, 1967) the design requirements just outlined were adhered to, and again no sign of a positive contrast effect was obtained.

It might be well at this point to describe another approach to the problem of contrast effects which also avoids the difficulties pointed out by Spence (1956). This approach was used in an experiment on rats by Collier and Marx (1959). Three groups of rats were trained in a bar-press apparatus with sucrose solutions used as reinforcers. The groups differed in terms of the concentration of sucrose delivered during magazine training. The concentrations used were 4, 11.3, and 32 percent. When bar-press training was begun following 8 days of this magazine training, the concentration used as the reinforcer was 11.3 percent for animals of all 3 groups. Thus, when going from magazine training to bar-press training the 4 percent group (to designate the groups in terms of the magazine-training concentration) received an upward shift and the 32 percent group a downward shift in concentration. During the 10 days of bar-press training, even though the reinforcer was the same for all animals, the bar-press

[10] See Schrier (1967) for details.

[11] For current treatments of these concepts in relation to problems of reinforcement see Capaldi (1967) and Amsel (1967).

rates of the three groups differed significantly with the differences in the direction of contrast effects. The 4 percent group showed a greater frequency of bar pressing than the control group, that is the 11.3 percent group, and the 32 percent group showed a lower frequency of bar pressing than the control group. Although the basic experimental design employed by Collier and Marx is sound, recently completed research by Dunham and Kilps (1969) indicates that, somewhat surprisingly, the results of this widely cited study probably had nothing to do with the shifts in the concentration of the reinforcer following magazine training. Dunham and Kilps present strong evidence, based on 3 separate experiments, that the differences in bar-press rates in the Collier and Marx study might well have been the result of persisting differences in the body weights of the subjects which were produced by the intake of different concentrations of sucrose during magazine training. In one of their experiments, Dunham and Kilps were able to produce "contrast effects" by altering body weight in the absence of shifts in sucrose concentration. When body weight was held constant, in another of their experiments, no contrast effects were observed despite shifts in the concentration of the reinforcer. Body weight has long been recognized as one of the basic variables to be controlled in learning and reinforcement studies, but there was little reason to suspect before this that this variable could operate in as subtle a manner as that demonstrated by Dunham and Kilps. The Collier and Marx design has also been used in experiments with runways (Goodrich & Zaretsky, 1962; Spear, 1965), with pre-feeding in the goal box serving in place of magazine training. Contrast effects were not obtained; rather in each case, the speed of running after all animals were switched to the intermediate concentration, was ordered in accordance with the pre-feeding concentration.

Thus, we would have to conclude that there has as yet been no convincing demonstration of the positive contrast effect using the single-shift procedure. On the other hand, there have been many runway studies (see, for example, Ehrenfreund & Badia, 1962; Gonzales, Gleitman, & Bitterman, 1962; Di Lollo, 1964; Di Lollo & Beez, 1966; Roberts, 1966) that have been carried out since those by Crespi, Zeaman, and Spence. All of these studies taken together establish beyond a doubt the existence of the negative contrast effect. Indeed, we can go a step further and concern ourselves with the variables influencing negative contrast. The magnitude of the negative contrast effect is directly related to the extent of the downward shift in amount (Gonzales, Gleitman, & Bitterman, 1962; Di Lollo & Beez, 1966); its magnitude may be larger when animals are under high-drive level than when under low (Ehrenfreund & Badia, 1962); if we reduce the amount of the reinforcer by small steps, we seem to prevent its appearance altogether (Gonzales, Gleitman, & Bitterman, 1962); and we might not observe it in animals lower than the mammals (Lowes & Bitterman, 1967).

We mentioned earlier that Crespi (1942, 1944) regarded the postshift effects as emotion-induced and, hence, transitory. We might add at this point that one of the major alternative conceptions of the shift effects is that they are essentially perceptual in nature, involving the same mechanisms as do the context effects in psychophysics (Collier & Marx, 1959; Bevan, 1966; Helson, 1966). This latter approach is consistent with those which assume that the behavioral effects of a reinforcer are related to its stimulus properties (see pp. 627–631). The perceptual explanations, however, assume both positive and negative contrast effects, something which we have already indicated may not be justified.

Whether the contrast effects are viewed as emotional or perceptual in nature, they would be expected to decay as a function of practice following a simple shift in the amount of reinforcer. On the other hand, an associational interpretation would lead us to expect more gradual changes and more lasting effects (Capaldi & Lynch, 1967). In considering this question, we have to limit ourselves to the negative contrast effect for reasons already outlined. Crespi, himself, had no clear-

cut evidence of a decay; he merely indicated (1944) that, if contrast effects were emotionally based, they should decay. (Unfortunately, some subsequent writers have failed to distinguish between what has been hypothesized and what actually has been found.) In any event, it has usually been assumed that, at least if they are emotion-induced, the contrast effects should not only decay following a single shift in the amount of the reinforcer, but should be "temporary" or "transient," that is to say, should decay quickly. One problem that arises immediately is that the conclusion we draw depends on our view as to how long a temporary effect should last. In most of the experiments that have been done, there has been no clear-cut sign of a decay within the experimental period. However, in many of these instances (Crespi, 1942; Spence, 1956; Di Lollo, 1964), it could be claimed that the postshift period was too short (8–15 trials) to warrant a conclusion that the effects are long-lasting or permanent.

One study that has often been cited as showing that the shift effects are long-lasting, and, hence, not emotional in origin, is that by Collier and Marx (1959), described a few paragraphs ago, in which bar-press rates of rats were measured following shifts in the concentration of sucrose. There was no sign of a decay in the contrast effects over the 10-day postshift period (during which the animals were given over two hundred reinforcements). However, as we have already mentioned, the outcome does not appear to be related to shifts in the quantity of the reinforcer.

There are also problems connected with studies which purport to have demonstrated a decay in the contrast effect. For example, the conclusion drawn in a study by Gonzalez, Gleitman, and Bitterman (1962) regarding a decay is based on rather limited evidence (the last data point of the experiment). On the basis of the data currently available, we would have to conclude that the assumption that the contrast effects decay rapidly has not yet been adequately tested.

It will be recalled that Crespi and Zeaman concluded that the change in performance level following a shift occurred very rapidly. Indeed, their reports led to a revision of one of the major theoretical systems of the day, that of Hull (1943). As we mention above, Hull had conceived of reinforcer amount as influencing strength of learning (habit strength) directly. Learning, in turn, is usually regarded as something that changes relatively slowly. Thus the change in reinforcer, particularly in the upward direction, should have resulted in a slower change in performance level than turned out to be the case. Have subsequent single-shift studies confirmed this aspect of the findings of Crespi and Zeaman? The situation is somewhat similar to that for the decay problem because the answer seems to depend on what is defined as a "rapid" change. Judging by the conclusions that have been drawn, different people have used different definitions. If we apply the term only to studies in which the changes in performance (relative to the control level) were nearly complete within the first 3 or 4 trials following a shift in amount of reinforcer, we find that at least 3 of the later studies fall in this category (Spence, 1956; Di Lollo, 1964; Schrier, 1967). However, there are a few experiments (Di Lollo & Beez, 1966) in which the rate of change can be reasonably described as being gradual. Such qualitative judgments are rather tenuous and merely emphasize the need for understanding the variables influencing the rate of change in performance and for quantitative analysis of the data. Whatever the case, debate on the role the amount of reinforcer plays in the learning process is still with us to some extent (Pubols, 1960), although the trend today seems to be to view amount as influencing motivation (see pp. 805–807) rather than "learning" per se.

Repeated Shifts in the Reinforcer

There are a variety of ways in which repeated shifts can be accomplished. For example, monkeys can be given (Schrier, 1961) test sessions in which they are trained to displace an object covering a foodwell that is baited

with food (such as sugar or banana-flavored pellets or peanuts). The response measure is latency of displacement of the object. During each test session, one of a set of amounts of food is used for a block of several consecutive trials and then the amount is changed for the next block of trials. The order in which the amounts are used is varied from test session to test session. In another procedure, commonly used with rats and somewhat inappropriately called "differential conditioning," training is given each day in two straight alleys, one painted black and the other white. A larger amount of food is placed in the goal box of one alley than in the other. An important common feature of the monkey and rat procedures is that the amount of reinforcer, though varying, is predictable on all or most trials. In the procedure used with rats, different cues (black or white start box), associated with the different amounts are available before the instrumental response occurs. In the procedure used with monkeys, the amount to be used for a given block of trials is predictable once the first reinforcement occurs. Shifts in amount of reinforcer given a subject are referred to as "systematic" whenever they are carried out in such a way that the amount to be used is predictable. Studies have also been done using a "random shift" procedure in which the amount was varied randomly from trial to trial, with no differential cues to indicate which amount was the current one.

Systematic shifts Repeated systematic shifts have almost always been used in amount of reinforcer studies in which the subjects have been monkeys, primarily because the time, effort, and expense involved in handling these animals usually precludes testing them in large enough numbers to use the constant-reinforcer approach. One of the earliest studies of this type was carried out by Meyer (1951). His animals were given a series of object-discrimination-reversal problems in the Wisconsin General Test Apparatus (see Chapter 17). For each problem, a new
Figure 15.8. Mean number of reversal errors by 8 rhesus monkeys (*Macaca mulatta*) during successive blocks of discrimination-reversal problems. Each curve represents a different combination of prereversal (preshift) and postreversal (postshift) amounts of reinforcer. (After Meyer, 1951.)

pair of junk objects[12] was presented, and depending upon the problem, response to the correct object was reinforced with either one or three pieces of food (raisins or peanuts, depending on the preference of the individual animal). After a number of trials, the discrimination was reversed; the correct object was made the incorrect, and the incorrect one, the correct. On these reversal trials, the amount of reinforcer either remained the same as it was on the prereversal trials or was shifted to the larger or smaller reinforcer. After 3 additional discrimination reversals involving the same pair of objects, a new pair of junk objects was used and the procedure repeated, again with some reversals involving upward or downward shifts in the reinforcer relative to that on the prereversal trials, and some involving no shifts. The frequency of errors was very low throughout the experiment because the animals had had extensive training on object-discrimination-reversal in previous experiments. Despite this, reinforcer level clearly influenced the outcome.

[12]Common, small household and other objects such as a thread spool and a rubber heel. Such objects differ in several attributes (color, form, size, and other characteristics), making possible many different problems.

Performance on the postshift trials (Figure 15.8) was significantly better when the postshift amount was the large than when it was the small regardless of the preshift amount. This means that the different amounts had significant effects on performance, but it does not tell us anything about reinforcement-context. For information about the latter, we must examine the effects of the postshift amounts in relation to the different preshift amounts. When we do this we find that on the average, fewer postshift errors were made with the large postshift reinforcer when the preshift reinforcer had been the small, rather than a large—a positive contrast effect; similarly, more errors were made with the small reinforcer when the preshift reinforcer had been the large, rather than the small—a negative contrast effect. The statistical tests that were carried out did not provide a basis for judging the reliability of the contrast effects. Anticipating some recent trends (Collier & Marx, 1959; Helson, 1966), Meyer suggested the possibility of treating reinforcing effects in terms of adaptation level concepts.

Whenever the repeated-shift type of variable reinforcer procedure has been used in studies of effects of amount of reinforcer on discrimination learning, a positive relationship has invariably been reported (see, for example, Meyer, 1951; Schrier & Harlow, 1956; Lawson, 1957). On the other hand, when the constant-reinforcer procedure has been used, relatively few investigators have found such a relationship (Reynolds, 1950; Schrier, 1956), while many have found no relationship at all (Reynolds, 1949; Furchgott & Rubin, 1953; Maher & Wickens, 1954; McKelvey, 1956). Two studies of similar design, one with rats (Lawson, 1957) and one with monkeys (Schrier, 1958), have been carried out in which the constant- and variable-reinforcer procedures were directly compared. In the Lawson study, only a small and nonsignificant difference was found in the brightness-discrimination performance of a large-reinforcer and a small-reinforcer group. On the other hand, in the case of a third group which repeatedly received both the large and small amounts, the brightness-discrimination performance was considerably better when the reinforcer was the larger amount of food. In the Schrier study, 2 amount-of-reinforcement functions were compared. One was based on the learning-set performance of 4 groups, each receiving a different amount of reinforcer (1, 2, 4, or 8 food pellets) for correct responses on a series of object-discrimination problems. The other amount-of-reinforcement function was based on the performance of a group of animals for which the amount of reinforcer was varied from problem to problem, so that they repeatedly received all 4 of the amounts that were used for the 4 constant-reinforcer groups. The upward slope of the amount-of-reinforcement function was significantly
Figure 15.9. Relationship between discrimination performance of rhesus monkeys (*Macaca mulatta*) and the amount of reinforcer, using the constant-reinforcer and the variable-reinforcer procedures. The amounts are plotted on a logarithmic scale. Each point on the curve for the variable-reinforcer procedure represents the performance of the same group of 5 monkeys, whereas each point on the curve for the constant-reinforcer procedure represents a different group of monkeys. There were 4 animals in the group that received 4 food pellets for each correct response and 5 animals in each of the other 3 groups. (Nontransformed version of data from Schrier, 1958.)

greater for the variable-reinforcer group than for the constant-reinforcer groups (Figure 15.9). Thus, both the Lawson and the Schrier experiments clearly suggest that the repeated-shift type of variable-reinforcer procedure is more likely to produce differential amount effects on discrimination performance than is the constant-reinforcer procedure. This has also been shown for speed of rats in a runway (Bower, 1961) and, somewhat less directly, for response latency of monkeys (Schrier, 1961; 1962).

On the question of positive and negative contrast effects, generally speaking the results of both the studies by Lawson (1957) and by Schrier (1958) conformed to expectations based on contrast: In these studies, performance levels were lower for the small amounts when the variable-reinforcer procedure was used than they were for the same amounts when the constant-reinforcer procedure was used. In general, the same was true, but in the opposite direction, in the case of the large amounts. However, neither experiment was designed with the separate positive and negative contrast effects in mind, so tests of significance of these were not conducted. Thus, whereas these studies can be regarded as providing evidence for reinforcement-context effects in the sense that the two procedures produce different results, they must be regarded as only suggestive on the question of such effects as positive and negative contrast. There have, however, been some repeated-shift studies in which tests for contrast effects were carried out. In one, a differential conditioning study (Bower, 1961) in which speed of running of rats was measured, a negative contrast effect was found, but there was no sign of a positive contrast effect. In another study (Leary, 1958) a significant positive contrast effect was reported. That experiment involved serial discrimination learning by monkeys and the method of carrying out the shifts was somewhat similar to that of Meyer (1951) in the experiment described above. All in all, it may be concluded that results of repeated-shift studies of the type discussed so far are in agreement with those of single-shift experiments in that all have shown trends in the direction of negative contrast. On the other hand, trends in the direction of positive contrast have been seen more often in repeated-shift than in single-shift studies.[13]

In a few instances, the effects of repeated shifts in the reinforcer have been in directions opposite to contrast. Marx and Pieper (1962, 1963) carried out two studies which were like the earlier one by Collier and Marx (1959), which was described on page 633, except that repeated shifts were involved. They regularly alternated sessions of magazine training during which one concentration of sucrose was presented with sessions of bar-press training during which another concentration was given as the reinforcer. In one case (Marx & Pieper, 1963), for example, during the first four days of bar pressing, a group of rats which received a 64 percent concentration periodically during magazine training and an 8 percent concentration (on an FI 1-minute schedule) during bar-press training showed a higher rate of bar pressing than a control group which received an 8 percent concentration during both magazine and bar-press training. It was not until the following 4 bar-press days that the expected result developed, that is performance differences in the direction of negative contrast. The conditions under which these unusual early shift effects occur are not clear as yet.[14] The alternation between

[13] For this reason, it is somewhat surprising that the two recent major reviews of the literature on effects of shifts in the amount of reinforcer (Black, 1968; Dunham, 1968) fail to mention any of these repeated-shift studies. Both reviewers conclude, as we have, that there is very strong evidence for a negative contrast effect. Both also conclude that there is no evidence for a positive contrast effect. Although it is true that, in a majority of the studies on the question, there has not even been a trend in the direction of positive contrast, such a trend has consistently been seen in studies having the following in common: (a) simultaneous two-choice discrimination problems were used; (b) only one choice was reinforced; (c) a repeated-shift procedure was employed.

[14] Because the conditions in the studies by Marx and Pieper were similar to those employed by Collier and Marx (1959), it is quite possible that differences in the animals' weights influenced Marx and Pieper's results also (see the discussion of the findings of Dunham and Kilps [1969] on page 634).

magazine training and bar-press training may not be critical because Anderson (1965) found similar effects in bar-press experiments on monkeys in which the concentration was alternated during successive periods of bar-press training. In none of these cases has the opposite effect persisted, but it should be kept in mind that reinforcement-context effects are not necessarily contrast effects.

It will be recalled that with the single-shift approach both gradual and rapid changes in behavior have been reported following a shift in amount of reinforcer. The appropriate analyses in the case of repeated shifts (that is, analyses of the changes in behavior following each shift in the series of shifts) have not been made, so there is no basis for comparison. However, it can be said that, typically, when repeated shifts are used (Meyer, 1951; Schrier & Harlow, 1956; Schrier, 1958), changes in performance levels under the different amounts of reinforcer are seen which are chiefly in the direction of greater differences in the effects of the different amounts and which seem to take place over the course of many trials. Furthermore, these changes in performance levels seem to reflect, in part at least, a learning process which has to do with the discrimination or the perception of the different reinforcers (Meyer, 1951; Schrier & Harlow, 1956; Hulse, 1960, 1962). This learning seems to be independent of the learning associated with the learning task itself, though it is not easy to separate the two because they are usually taking place simultaneously. Perhaps the typical discrimination learning situation can be conceived of as involving at least 3 partially independent processes: discrimination of the cues, discrimination of the reinforcer, and association of the reinforcer with the appropriate cues.

With the single-shift method, although decay in the contrast effect with practice has been reported, there have also been cases in which it has proved relatively persistent. In none of the repeated-shift studies in which the results have been in the direction of contrast (Meyer, 1951; Lawson, 1957; Leary, 1958; Schrier, 1958; Bower, 1961) has there been any evidence of a diminishing of the effects of the shifts with practice. However, it cannot by any means be concluded that the effects are permanent, because there is no strong evidence to indicate that the performance levels in question were at the asymptote at the end of the experiments. This is an interesting question because any account of contrast effects which assumes that they are primarily the result of perceptual changes could easily explain the persistence of these effects over the course of a large number of shifts in the amount of reinforcer, but it is doubtful that an account which treats them as strictly emotional phenomena could. So long as the set of stimuli in a series remains constant, there is no reason to believe that, once the initial adjustments are completed, the perception of any of the stimuli would change.

Random shifts How would animals behave when different amounts of reinforcer
Figure 15.10. Speed of running of rats in a straight-alley apparatus with the average amount of reinforcer held constant over trials, but with different ranges of variation in amount as indicated in the legend. The response measure was the time taken by the animal to traverse a distance for 4 ft, starting at a point several inches beyond the start box and ending at a point a few inches in front of the food cup in the goal box. The ordinate represents the mean of the reciprocals of these running times. (After Beier, 1958, as reported by Logan, 1960.)

are introduced in random order and no cues are available to indicate which amount is present on any particular trial? Would, for example, the animal's performance be influenced more by one amount than another, or would its performance be a simple function of the average amount received? Employing a straight-alley apparatus, Bier (1958, as described by Logan, 1960, pp. 74–77) gave 3 groups of rats an average of 7 pellets per trial. One group was given 10 pellets on a random half of the trials and 4 pellets on the other half. The conditions for a second group were the same, except that the 2 amounts used were 13 pellets and 1 pellet. A third group received 7 pellets on all trials. The mean running speed of the 10- and 4-pellet group was slightly faster than the mean for the 7-pellet group. The running speed of the 13- and 1-pellet group was considerably slower than that of the other two groups (Figure 15.10). Additional data obtained using these procedures (Logan, 1960) suggest that the relationship of the performance of animals receiving random shifts in amount of reinforcer to that of animals receiving a constant amount depends both on the range of amounts and the average amount.

Two-choice situations, either choice reinforced An interesting variation on the repeated-shift procedure involves reinforcement of both alternatives in a two-choice situation. On each trial, the choice of one stimulus is reinforced with one amount of food, whereas the choice of the other stimulus is reinforced with a different amount. This procedure was used by Spear and Hill (1965) in an experiment with rats in a **T** maze. In one instance 3 groups of rats always received 1 pellet of food in 1 goal box of the **T** maze. The treatment of the groups differed in that one of the groups received 1 pellet, the second received 2 pellets, and the third 10 pellets in the other goal box. Forced-choice trials were mixed with free-choice trials to ensure the rats gained experience with both goal boxes. By the end of the experiment, all animals were consistently choosing the side containing the larger amount. This behavior developed more quickly in the group receiving 10 pellets in the large-reinforcer goal box, than in the one receiving 2 pellets. The larger the amount of food they received on the large-reinforcer side, the slower the rats ran to the box containing the small amount of food—a negative contrast effect.

Can positive contrast be demonstrated using the procedures of Spear and Hill? The answer seems to be "No" (Spear & Spitzner, 1966), as it is in the case of the other procedures previously described.

Meyer, Lo Popolo, and Singh (1966) trained monkeys concurrently on four 2-choice visual discrimination problems. Responses to either stimulus of each pair were reinforced using different quantities of food. The ratios of the amounts used for the four pairs were 8:4, 4:2, 2:1, and 8:1, respectively. During the training period, following each choice trial, the stimulus that was not chosen was presented alone and reinforced. The purpose of this procedure was the same as the forced trials in the Spear and Hill study. Following this training, tests were carried out in which the 8 stimuli involved were arranged in new pairs, there being 24 possible new pairs. However, the subjects continued to be trained with the original pairs throughout this period. The results of those tests with new pairs of stimuli in which both members of the pair had been reinforced with equal amounts of food during original training are of most interest here. What, for example, would an animal do when it was faced with two stimuli which had been associated earlier with equal quantities of the reinforcer (one piece of food, for example), but which had at the same time been paired with stimuli associated with different quantities of food (say 2 pieces in one case and 8 pieces in the other)? The stimuli involved will be designated as "1 (2)" and "1 (8)," with the first number in each case indicating the amount that had been associated with the stimulus during original training and the number in parentheses indicating the amount

associated with the stimulus with which that stimulus had been paired in original training. A prediction based on contrast would lead us to expect a choice of the 1 (1) stimulus over the 1 (8) stimulus because the negative contrast would be greater in the case of the latter stimulus. In fact, 7 of the 8 animals chose the 1 (8) stimulus more frequently than the other. The eighth animal split its choices evenly. In all other cases, there was either no consistent difference in the frequency of choice—4 (2) as opposed to 4 (8) and 8 (1) as opposed to 8 (4)—or else the difference was in the direction of contrast—2 (1) chosen more frequently than 2 (4). (For a discussion of the possible reasons for these outcomes see Estes, 1966.) Once again, we are reminded that reinforcement-context effects other than contrast are possible.

Behavioral Contrast

Although the topic of behavioral contrast does not really belong in this section of the chapter, we mention it here because behavioral contrast bears at least a superficial resemblance to the kind of contrast phenomena we have been considering up to now and might conceivably involve a similar mechanism.[15] It was first described by Reynolds (1961), who first trained pigeons to peck a key with reinforcement occuring on a VI schedule. After the animals' response rates appeared to stabilize, Reynolds began alternating, within sessions, periods in which key pecking was reinforced on the same VI schedule with periods in which key pecking was not reinforced (extinction). The key color during extinction periods was green or blue and during VI periods it was red or orange. This kind of procedure is called a "multiple schedule of reinforcement," which is one type of operant discrimination training. This term is commonly used to describe repeated shifting among two or more schedules when the schedule changes are accompanied by corresponding changes in external stimuli. Reynolds found that response rate was higher on the VI schedule when it was a component of the multiple schedule than when it was the only schedule. This would be positive behavioral contrast (see Figure 17.13, p. 777). Reynolds (1961) introduced control conditions which suggested that the increased rate on the VI component of the multiple schedule was the result of the lowered frequency of reinforcement in the other component of the multiple schedule, rather than the lowered rate of responding. For example, no behavioral contrast was found when the multiple schedule consisted of the VI component and a time-out component, during which neither the response key nor the test chamber was illuminated. Under such conditions, pigeons tend to have a very low response rate or do not respond at all. Similarly, no behavioral contrast was seen when the multiple schedule consisted of the VI component and one involving reinforcement for not responding for either 50 or, in some cases, 75 seconds. One of the components does not have to be extinction in order to produce behavioral contrast, but may simply be a schedule, such as another VI schedule (Findley, 1958), which programs a lower frequency of reinforcement. Negative behavioral contrast can be produced by increasing the frequency of reinforcement in one component of a multiple schedule (Reynolds & Limpo, 1968).

Some interesting parallels between the work on behavioral contrast and that on contrast produced by shifting the amount of reinforcer have developed. Terrace (1966b) has recently reported that the magnitude of behavioral contrast tended to diminish over the course of 60 daily test sessions during which a multiple VI-extinction schedule was in effect. Terrace concluded that behavioral contrast is the result of "frustration, or similar emotional responses." On the other hand, Bloomfield (1967), using procedures that seem to be somewhat more similar to Reynolds' than to Terrace's, found no sign of a decay in behavioral contrast over the course of the same number of daily test sessions. In

[15] For a different perspective on behavioral contrast see Chapter 17.

Bloomfield's experiment, blocks of daily test sessions (with most blocks consisting of 20 test sessions) during which a VI schedule was used were alternated with blocks of test sessions during which a multiple VI-extinction schedule was used. In addition to the behavioral contrast, Bloomfield reported some upward shifts in the rate of responding during successive blocks of sessions involving only the VI schedule. Because of this, he emphasized the need for final, as well as initial, measures of baseline or control rates of responding. Considering some of the difficulties encountered in interpreting the results of experiments involving shifts in amount of reinforcer, we might also suggest the use of unshifted control groups in experiments on behavioral contrast.

REINFORCING BRAIN STIMULATION

To understand the excitement that was created by the first announcements of positive reinforcing effects from direct electrical stimulation of regions of the mammalian brain, it is necessary to recall the context in which this news was received. Of all the areas of experimental psychology, learning seemed to be the least advanced in terms of the discovery of anatomical and physiological correlates of psychological processes. Almost all psychologists agreed that the effects of experience must somehow be coded, stored, and retrieved from the nervous system; and almost all would also have agreed that some unique physiological event (or events) must occur on those occasions when we say "reinforcement occurred." Yet, after more than fifty years of laboratory research, not a single shred of direct evidence to support either of these beliefs had been found.

It was under these circumstances that the announcement by Olds and Milner (1954) was made. They were investigating the behavioral effects of stimulating various regions of the rat midbrain, a procedure which might be expected to increase the level of activation of the animal (see Chapter 18). They noticed that when they stimulated one animal, he repeated whatever response he had made just prior to stimulation, and that by the judicious use of the electrical stimulation, they could cause the animal to repeat responses or they could shape him toward entirely new responses (Olds, 1955).[16] In other words, they had found a positive reinforcing stimulus that by-passed the peripheral mechanisms normally activated by reinforcers. Later examination of the animal's brain showed that the stimulating electrodes had been placed in the general region of the septal area, a portion of the forebrain and quite distant from the midbrain. A fortunate error (in the placement of the electrode), plus investigator astuteness (to appreciate the importance of the observations) are the two foremost ingredients of serendipity in science. The third ingredient is, of course, communication of the results. Happily, all three were present on this occasion.

Here then was a technique that promised to uncover the locus of reinforcement. And if the site of the reinforcing stimulation could be specified, what was to prevent the associated neural pathways from being explored, with the eventual discovery of "where" the confluence of sensory and motor activities joined with the reinforcing stimulation to produce the changes that must underlie learning? Such thoughts certainly occurred to many who heard or read about the Olds and Milner experiments during 1953 and 1954: at last the psychology of learning had some solid clues as to where to start the search for the neurological substrates of reinforcement and possibly even of motivation and of "pleasure" (see Olds, 1956).

The next few years saw a rash of investigations of this phenomenon. They fell, for the most part, into two groups: those that sought to specify more precisely the loci in the brain

[16]The abbreviations most frequently used when referring to the stimulation are ICS ("intracranial stimulation"), and ESB ("electrical stimulation of the brain"). Both are appropriately neutral regarding anatomical and physiological factors.

that gave reinforcing effects, and those which asked whether the reinforcing effects thus produced were indeed the same as the effects with which psychologists long had been familiar.

Some Problems of Technique

A few facts about techniques are needed to understand the results that have been obtained in the studies. Chronic electrodes for recording or stimulating central nervous system tissues were developed in the 1930s (Hess, 1932) and had been used successfully to stimulate portions of the central nervous system to produce pain-like and fear-like responses, and escape and avoidance learning (Delgado, Roberts, & Miller, 1954).

For stimulation purposes, the electrodes
Figure 15.11. A frontal section of rat brain showing an electrode track and a corresponding plate, Figure 34a in the rat brain atlas of König and Klippel (1963). The electrode was lowered through the cortical and subcortical areas of the right hemisphere until the tips of the electrode were thought to be in the region of the lateral hypothalamic nucleus (*hl* in the atlas). In this case, the placement was quite satisfactory. The brain sections usually are cut at an angle to the electrode track, making it easier to keep the sections in one piece. This section was deliberately sectioned in the same plane as the electrode track so that the full course of the track could be shown. The brain was frozen, sectioned at 40μ, and stained with cresyl violet. The triangular gash in the left hemisphere is a mark made in the brain before sectioning as an aid to later orientation.

usually are quite gross: One or more pieces of wire may be used in the assembly, and the diameter of each piece of wire may be .010 in. or more. Thus, in comparison with the size of brain structures, the electrodes may be very large indeed. The electrodes usually are insulated except at the tips, and if a bipolar (two-wire) electrode is employed, the current flows from one tip to another. If these tips are close together, the stimulation will be restricted to a fairly small area, for the current apparently spreads very little to tissue more than 1-2 mm from the tips of the electrode (Valenstein & Beer, 1961; Valenstein, 1966). The early electrodes frequently were made of copper or silver wires, but both of these proved to have deleterious effects on tissue (Rowland, MacIntyre, & Bidder, 1960). At the present time, stainless steel or platinum are the most frequently used materials.

Successful implantation of an electrode requires an atlas of the brain, a means of fixing the head of the animal in a known position, and a device for moving the electrode the proper distance in the desired direction. The brain maps are created by taking serial sections of a brain while it is in some clearly specified orientation. Then, by starting from the same bench marks used in constructing the brain atlas, one can determine the direction in which to move, and how far to move, to bring the tip of an electrode to the desired location. With the animal under general anesthesia, the electrode is lowered through a small hole that has been made in the skull. When the desired coordinates have been reached, the electrode is cemented to the skull leaving only the connector exposed. One or more such electrode sets may be implanted. Usually, the first stimulations are postponed for about a week, on the theory that local trauma in the region of the electrodes will then have subsided. (Techniques for implanting chronic electrodes are described in several chapters in Sheer, 1961.)

Of course, once the experiment is completed, the exact placement of the electrodes must be ascertained. After the animal has been anesthetized, the tissue is perfused with saline (to flush out blood) and formalin (to kill and preserve the brain tissue). Later, the brain may be prepared for slicing by freezing it or by embedding it in a supporting medium (such as paraffin or celloidin), and then cut into thin sections. Usually the sections are stained to reveal special characteristics, such as nuclei or fiber tracts, and then mounted for ease of examination. Once the sections containing the electrode track are located, the corresponding plates in a brain atlas are consulted, and the estimated position of the stimulating tips of the electrode is determined. An example of a typical section from an animal, and the page of a brain atlas that
Figure 15.12. The major parameters manipulated during electrical stimulation of the brain. When discrete rectangular pulses are utilized, typical pulse durations are 0.1 or 0.2 msec, and the most common pulse frequency is 100 pulses/sec. Thus, only 1-2 percent of the total train of stimulation is actually made up of stimulating pulses. When sine wave stimulation is employed, practically all of the train duration provides active stimulation. Hence, the currents needed for sine wave stimulation are much lower than for discrete pulse stimulation. When one calculates the total charge per reinforcement, however, sine wave stimuli must have larger charges to produce equivalent behavioral effects of discrete pulse stimulation.

includes the area invaded by the electrode track, are shown in Figure 15.11. Although the amount of tissue damage from such electrodes is rather extensive, it should be borne in mind that behavioral or physiological deficits very rarely result from unilateral tissue loss in the regions through which such electrodes are passed.
Figure 15.13. A simple circuit for electrical stimulation of brain tissue. F = fuse (1 amp); S_1 = main power switch; S_2 = stimulation switch; T_1 = isolation transformer; R_1 = 10-turn potentiometer, 100K ohms, 2 watt; R_2 = fixed resistors, 1 megohm each; R_3 = fixed resistors, 1K ohm each; E = voltage monitor; I = current monitor; A = animal. S_2 usually is a double pole-double throw relay, with associated timing circuitry to control the duration of the stimulation train. R_3 may be any convenient value; 1 K ohm usually is satisfactory when current is monitored with an oscilloscope. R_2 is large relative to the impedance of the preparation, thus providing moderately good current regulation. With typical bipolar stainless steel electrodes, the preparation will vary between 10,000 and 20,000 ohms in most cases when 60 Hz stimulation is used. Current and voltage monitors should have high internal impedance values, as do oscilloscopes. The leads between S_2 and the animal should be kept as short as possible. Both sides of the circuit should be interrupted by S_2 to avoid accidental production of a difference in potential between the electrode and metal parts of the animal's chamber. When this occurs, an animal will lick or rub his nose on the metal, thus stimulating himself *ad libitum*. An additional degree of protection is offered by eliminating from the chamber all metal parts or all electrical sources other than low voltage direct currents. Retractable bars and drinkometer circuits are especially likely to provide sources of alternating current which the animal will discover, and from which he will obtain stimulation.

It is extremely important that the parameters of the electrical stimulation be described clearly in each experimental report. The major parameters are: frequency, duration of individual pulses or cycles, intensity, and train length. In addition, stimulation may be monodirectional or bidirectional. These dimensions are illustrated in Figure 15.12. In almost all recent work, bidirectional stimulation is employed, for monodirectional stimulation is more destructive of tissue. No special generators need be employed, unless the manipulation of pulse frequency or duration is a major concern. For many behavioral studies, ordinary 60 Hz current from the house line (adequately isolated, of course) is quite satisfactory. A typical circuit for such stimulation is given in Figure 15.13. For experiments in which precise maintenance of current levels
Figure 15.14. Rate of responding as a function of the total electrical charge per stimulation. Average results for 10 rats. Six values for pulse intensity (0.5–4.0 mA) pulse frequency (23–138 pulses/sec), and pulse duration (0.28–2.65 msec) were used. Each animal was exposed to every value on 2 separate occasions. During testing, responses were reinforced with the electrical stimulation on the average of every 16 sec (a variable interval 16-sec reinforcement schedule). Each reinforcement consisted of a 0.5 sec train of bidirectional rectangular stimulus pulses. (After Keesey, 1962.)

is necessary, more elaborate current regulating circuits are needed.[17]

Intensity of stimulation Rate of self-stimulation increases as the intensity, pulse frequency, and pulse duration are increased (see, for example, Keesey, 1962), but at the higher intensity values, response rates may decline somewhat; the implications of these declines will be discussed later. For the moment, let us consider only the rising portion of the rate-intensity function. Each of the parameters of stimulation represents an independent means of manipulating the total electrical charge per reinforcement: Is it possible that the reinforcing effects of brain stimulation can be simply summarized in terms of the total charge (that is, in coulombs) per reinforcement? If this were true, we would expect the same response curves to be produced regardless of which parameter (that is, intensity, frequency, or duration) is manipulated. Within limits, this does appear to be true. Figure 15.14 summarizes the results of a series of rate-intensity determinations on the same rats, with frequency, intensity, and pulse duration as the parameters. The frequency and intensity curves are quite similar over the range of the values of the charge which they have in common. Note, however, that the pulse duration curve is displaced, so that a greater total charge per reinforcement is required to produce a given rate of self-stimulation, indicating that duration is a less efficient way of delivering a given charge to the tissue. Such relative loss of efficiency is not unexpected, for as pulse durations are increased, direct current conditions are approximated, and these are ineffective as reinforcers.[18]

[17]The intensities of stimulation needed to produce reinforcing effects are far greater than any naturally occurring electrophysiological changes in brain areas, and therefore could be called "nonphysiological" stimulations (see p. 254).

[18]A portion of the loss is probably due to a polarization at the electrodes. Stimulation with direct current also creates lesions, which further reduces the efficiency of the stimulation.

Would extremely brief pulses prove to be especially effective in self-stimulation? Probably not, since it seems likely that the compensatory increases in frequency or intensity that would be needed to maintain responding would soon reach their limits, with high intensities producing trauma and high frequencies (1000 Hz and above) losing reinforcing characteristics (Ward, 1959).

Do animals show any indication of sensitivity to a charge-per-reinforcement dimension? The answer seems to be "yes." For example, if a rat is allowed to control the length of a train of stimulating pulses, he will systematically adjust the train length to counter manipulations of pulse intensity and frequency by the experimenter (Keesey, 1964). We should not conclude from this that all dimensions of the stimulus can be summarized in terms of total charge, for as we have seen, the reinforcing effects of a given charge are in part determined by pulse duration (Keesey, 1962), and possibly also by frequency and wave shape (see Su et al., 1966).

Locus of Stimulation

The regions where positively reinforcing self-stimulation effects can be obtained are scattered quite widely throughout the deeper, subcortical regions of the brain. For the most part, the locations are in the medial forebrain bundle and closely related structures. Positively reinforcing areas are frequently found in phylogenetically old regions of the central nervous system; few positive loci have been found within the cortex or neocortex. No single anatomical system is known which could tie together all these areas, but some common elements among the areas have been discovered. For example, if anterior and posterior electrodes are placed in the medial forebrain bundle of a rat and then bilateral lesions are made at the anterior sites, self-stimulation through the posterior electrodes is diminished, although not eliminated. However, if the lesions are made at the posterior sites, self-stimulation through the anterior electrodes is abolished (Olds & Olds, 1965).

These interactions are thought by some to indicate the existence of a final common pathway for positive reinforcing effects, with the posterior portions of the medial forebrain bundle and the lateral hypothalamic area as the route through which the activity must flow. A somewhat similar conclusion, based on other forms of indirect evidence, was reached by Morgane (1964) and by Stein (1964).

However, there is considerable evidence against this theory of a single positive reinforcement system. For example, Valenstein (1966) reports the results of several experiments in which rats with positive septal placements were then given bilateral lesions in various areas of the brain, including, in some cases, lesions in the medial forebrain bundle and lateral hypothalamus. Destruction of the lateral hypothalamic areas seriously impaired the regulation of body temperature, caused the animals to stop eating and drinking, and produced other signs of the "lateral hypothalamic syndrome" (Teitelbaum & Epstein, 1962). Only by special nursing, sometimes for several weeks, was it possible to bring some of those animals back to health. However, once recovered from the operations, these rats self-stimulated at rates equal to, or higher than, the response levels they had reached during pre-operative tests. On the basis of these, and other studies, Valenstein concludes: " . . . it is unlikely that there is any essential pathway or critical locus for the self-stimulation phenomenon in the limbic system or medial forebrain bundle-lateral hypothalamic area" (p. 180). The failure to eliminate reinforcing effects by surgical destruction of the possible pathways between sites of stimulation and other brain areas suspected of playing a role in self-stimulation "may suggest that some humoral transmission is at work" (p. 182).

Of course, it would be incorrect to assume that such lesion methods leave the electrode tips suspended in limbo; it is impossible in any one animal to isolate the electrode completely from all surrounding tissue, but when the results of many studies with a great many animals are considered, we are left with the impression that there probably is no single positive reinforcement "system," in the sense that there is a single visual or auditory system. Instead, it seems that this work shows another example of the plasticity of the central nervous system, where alternative routes and integrating systems are available for many basic functions.

Evaluations of the behavioral effects of electrical stimulation usually are based on the rate at which the animal self-stimulates when delivery of the stimulation is contingent upon the emission of some simple response, such as pressing a bar. When exploring regions of the brain, some characteristic differences in rates of self-stimulation have been found. For example, in the septal area, rats ordinarily will self-stimulate at fairly high rates, for relatively long periods. In lateral or posterior hypothalamic regions, even higher response rates and greater persistence are typically found. In other areas, higher or lower rates may be found, and more or less steady patterns of responding may emerge. At the present time, only such relatively gross differences in the positive reinforcing effects attributable to locus of stimulation can be mentioned; more precise specification will probably require the use of less massive electrodes, and the development of behavioral techniques capable of detecting finer variations in reinforcing effects. For a summary of some typical results from mapping experiments, see Olds and Olds (1963).

On the whole, the use of self-stimulation rates to examine loci has shown that quite a few portions of the brain are likely to produce positive reinforcing effects; that most are neutral; that some are obviously noxious, and can be used much like other aversive stimuli; and that some are mixed, in that the animal will make one response to turn the stimulus on and another to turn it off (for example, Bower & Miller, 1958). Within the regions that seem to be purely positive, the behavioral effect does not appear until some

level of stimulation has been exceeded (in other words, there is an absolute-threshold effect). Then, as further increases in the amount of stimulation are made, the self-stimulation rate may increase, sometimes to be followed by a decline in rate even before there are any behavioral indications that the intensities are producing disruptive motor reactions. Still more intense stimulation may produce obvious signs of distress (such as vocalizing or frantic leaping), disruptive motor reactions, convulsive seizures, or combinations of all three. In most studies, intensities which produce any of these extreme effects are not used, even though the animals may continue to self-stimulate at such intensities if given the opportunity to do so. These upper limits to the usable intensities vary from locus to locus within the same animal, and between animals when all are given what appear to be the same electrode placements.

In light of these reactions to the higher ICS intensities, rate of self-stimulation sometimes may seem to be a misleading index of the reinforcement value of a given locus or set of stimulation parameters. For example, if each stimulation elicits a motor reaction which throws the animal to one side, we might hesitate to conclude that his low rate of self-stimulation reflects the actual reinforcing value of the stimulation. Usually motor involvement is not so gross, but the probability of some degree of interference becomes of considerable concern whenever the higher intensities of stimulation are applied.

Inspection of the temporal distribution of responding in self-stimulation situations reveals an orderly pattern of changes which frequently cannot be detected in the gross response rate. If the interresponse time (IRT) between each pair of responses is recorded, and the probability of each IRT is plotted as a function of the intensity of the stimulation, a systematic decline in both the shorter *and* the longer IRTs is revealed as intensity is increased. Since the suppression of short IRTs outweighs the suppression of long IRTs, the
Figure 15.15. Effects of increasing intensity of brain stimulation on rate of self-stimulation. Seven current levels were selected that

overall effect is a decline in response rate. An example of such changes in IRTs as a function of stimulation intensity is given in Figure 15.15. It is important to note that such changes in IRT patterns occur in the absence of grossly discernable motor reactions; the suppression of both the shorter and longer IRTs is not merely a reflection of overtly incompatible behavior elicited by intense stimulation.

Two strategies have been employed to minimize the potential distortion of the rate measure as an index of the value of the stimulation as a reinforcer. The first approach retains response rate as the index, but instead of reinforcing every response, reinforcement schedules are utilized which space the reinforcements so widely that the relative distortion that might possibly result from motor disruptions would have little influence on the average value of the response rates. Such reduction in the density of reinforcements through the use of variable interval reinforcement schedules (Beer, Hodos, & Matthews, 1964), or through reinforcement of interresponse times greater than some selected interval (J. Terman, 1968) have been successful in eliminating some of the distortions found in response rates when continuous reinforcement is employed.

A more direct approach is the elimination of rate itself as the primary index of reinforcement value. For example, Hodos (1965) and Keesey and Goldstein (1968) have evaluated ICS reinforcers through use of the progressive ratio method (Hodos, 1961; Hodos & Kalman, 1963). In using this procedure, the experimenter selects the increment to be added to each successive ratio requirement, and reinforces the last response in each of these blocks of work. For example, if the increment is 2, the 2d, 6th, 12th, 20th, 30th . . . responses would be reinforced. In this manner, the ratio of total responses to reinforced responses is progressively increased throughout the experimental session, until a point is reached where the subject no longer will emit responses. Of course, some practical criterion must be adopted to define the end of the session; 5 minutes without responding, or failure to complete a ratio in 15 minutes, is a common criterion for lever-pressing experiments using rats. The value of the largest ratio completed, or the average number of responses per reinforcement, are typical indices of the effectiveness of the conditions of reinforcement.

Still another approach (Valenstein & Meyers, 1964) utilizes a two-compartment chamber, with given stimulation parameters set to be delivered whenever—and for as long as—the animal is in the designated chamber. If the stimulation becomes aversive, he can escape; and if it proves to be of but modest reinforcement value, he may follow it with relatively little vigor as the programming device switches the "hot" side of the chamber from time to time. Typically, the stimulation is available in successive 1-min blocks appearing randomly on one or the other side. Thus, should an animal sit completely still, he would receive 50 percent of the possible

---

covered the effective range of stimulation for the animal. Every response was reinforced with a 0.5-sec train of stimulation; the frequency was 100 bidirectional pulses per second, each pulse lasting 0.2 msec. Electrode placement was in the lateral hypothalamus. *Top curve* shows the response rate as a function of stimulus intensity, showing a "typical" hypothalamic rate-intensity function, with marked positive acceleration once the "reinforcement threshold" is exceeded, and a slight decline at the very highest intensities. *Middle curve:* same results, plotted as IRTs per opportunity for each of the stimulation intensities. Note that the probability of a long IRT (that is, a slow response) is decreased as stimulation intensity is increased. *Lower curve* shows the same results, with the first 2 seconds of the IRTs expanded to show the effects of increasing stimulation intensity on the short IRTs (that is, rapid responses). Note that increasing stimulation intensity first increases, and then "suppresses" the shortest IRTs, especially those emitted while the stimulation from the previous response is still being delivered. (After Terman, Terman, & Kling, 1970.)
Figure 15.16. Two measures of the influence of intensity on the reinforcing effects of electrical brain stimulation. A rat with a hypothalamic electrode was allowed to stimulate himself (every response was reinforced), and also was allowed to move from side to side in a 2-chamber box, 1 side of which presented repeated bursts of stimulation. The "indifference" levels of stimulation and the points of "peak preference" appear to be highly similar as measured by these two methods. (After Valenstein & Meyers, 1964.)

stimulation, while if he were to respond quickly to the available cues, he could "follow" the stimulation as it is shifted from side to side and obtain almost 100 percent of the programmed stimulation. Comparisons of the shape of the function describing the percentage of stimulation received at various intensities with the shape of the typical rate-intensity function for the same animal (see Figure 15.16) show remarkable similarity.

Because motor skills are of minor importance in the shuttle box, it does not seem reasonable to ascribe the decline in the preference curve at higher stimulation values to "motor side-effects." Instead, it seems that the punishing consequences of the stimulation might account for a large proportion of this decline. Indeed, by the judicious manipulation of stimulation parameters, it might be possible to determine the relative contribution of various aspects of the stimulation to the positive reinforcing effects, the punishing effects, and the disruptive motor effects.

In such shuttlebox experiments, the stimulation ordinarily is delivered as short trains (such as 0.5 sec) of pulses spaced by brief (such as 1.0 sec) intervals. Thus, the over-all density of stimulation is not unlike that resulting from self-stimulation procedures in which every response is reinforced, and as in the self-stimulation situation, declines in the response curves at higher stimulation intensities are common. Lowering the stimulation density by increasing the interstimulation interval reduces or eliminates the higher-intensity decline. Similarly, enforcing lower stimulation densities in other situations also eliminates this decline. For example, the animal may be required to carry out a series of simple choice responses (Hodos & Valenstein, 1962) or emit a response chain involving 2 levers (Pliskoff & Hawkins, 1967). Or the experimenter may utilize a long variable interval schedule of reinforcement (Beer, Hodos, & Matthews, 1964) or reinforce only those responses separated by some selected minimum interresponse time (J. Terman, 1968). Each of these procedures has the same effect on the average response rate: the immediate post-reinforcement suppression of responding occurs infrequently because reinforcement occurs infrequently, and hence the decline in response indices is largely (or completely) eliminated.

When viewed as a whole, the results of these different procedures suggest that the reinforcing effects of electrical brain stimulation are increased as the stimulating current is increased, that the duration of the post-stimulation response suppression also increases as current is increased, and that if the conditions of the experiment allow the stimulations to be massed, an overall response decline may occur at the upper stimulation

values. This decline may occur in the absence of any noticeable conflicting or disruptive responses, and in such cases it seems reasonable to assume that there are aversive sensory consequences of massed stimulations. The similarity of these effects and those found when sucrose or saccharin solutions are presented in high concentration, large volume, and with short inter-reinforcement intervals (see p. 626) may serve to remind us that "aversive" need not always imply that the stimulation is painful.

Comparisons with Other Reinforcers

The very first studies indicated that the reinforcing effects of electrical stimulation could, in some cases, be even more potent than commonly used reinforcers. For example, in an "obstruction box" (Jenkins, Warner, & Warden, 1926), where an electrified floor separates the starting area from the point where the reinforcer is delivered, the intensity of foot shock needed to deter an animal from crossing the grid was higher for brain stimulation than for food (Olds & Sinclair, 1957). In another situation, where animals could press one bar to produce food pellets and another to produce electrical stimulation, some animals so neglected the food bar that eventually they died of starvation (Routtenberg & Lindy, 1965). Similarly, some adrenalectomized animals died when placed in a situation where pressing one bar produced small drinks of life-saving sodium chloride solution and the other bar controlled short bursts of brain stimulation (Eckert & Lewis, 1967). Additional examples of such self-deprivations arising from brain stimulation could be mentioned; there is no doubt that the stimulation is a powerful reinforcer. But why should animals fatally deprive themselves when they could easily survive by devoting just a small portion of their time to working for food or sodium chloride? A clue may be seen in the electrode placements: The electrode tips are aimed at the posterior hypothalamus, just lateral to the midline, from which are obtained very high rates of self-stimulation that are then further augmented by food deprivation (Olds, 1958a), by adrenalectomy (Eckert & Lewis, 1967), and possibly by other deprivation procedures. In the self-deprivation tests, the animals already have had some exposure to the brain stimulation; there is no satiation phenomenon to "turn off" this self-stimulation; and the increasing food or salt deprivation only causes still greater proportions of the total experimental time to be devoted to self-stimulation. Eckert and Lewis observed that all of their self-depriving animals did show increasing numbers of salt-producing responses during the test period, but some "did not learn fast enough" to survive. The wisdom of the body is considerable, but not infallible.

Extreme self-deprivation frequently is interpreted as an indication of some intimate relation between the site stimulated by the electrodes and the physiological system thrown out of balance. If the rat does not regulate his food intake, and devotes almost all his time to hypothalamic self-stimulation, does this not suggest that the electrical stimulation may (1) serve as a substitute for the food, and/or (2) distort the signals that communicate the need for food to the hypothalamic regulatory "centers"? Such reasoning is made plausible if we consider the relations between food-seeking behaviors and two hypothalamic areas. The ventromedial hypothalamus seems to mediate stop-eating behaviors, for its bilateral ablation produces overeating (see review by Teitelbaum, 1961) and its direct stimulation (Epstein, 1960) produces cessation of eating. In the lateral hypothalamus, a complementary region mediating "hunger" has been hypothesized, inasmuch as chemical (Epstein, 1960) or electrical (see, for example, Margules & Olds, 1962) stimulation of that area produces eating and food-seeking behavior, and its bilateral ablation or its anesthetization causes a reduction in drinking and eating, plus some finickiness in accepting food (see review by Teitelbaum & Epstein, 1962; and Powley & Keesey, 1970).

The type of difficulty faced by such "phys-

iological" interpretations of self-starvation may be mentioned briefly, for this also is pertinent to the more general question of why some electrical brain stimulation is positively reinforcing. Stated in the most simple terms, we might assume that the rat fails to eat when given the opportunity to work for both brain stimulation and for food because the brain stimulation somehow reduces his hunger. This effect might be the result of the brain stimulation providing input which is similar to that ordinarily present in the central nervous system when the animal is satiated, or it might reflect the blocking of the normal signals of deprivation by the brain stimulation. However, direct stimulation of lateral hypothalamic areas produces "stimulus-bound eating" and food-seeking behavior which implies increased (rather than decreased) hunger. Common sense would seem to suggest that stimulation which increases hunger should have punishing, and not positively reinforcing consequences, but the lateral hypothalamus is one of the most effective loci for self-stimulation electrode placements. Of course, it is possible that the brief trains of stimulation used in self-stimulation procedures might decrease hunger, while the much longer trains of stimulation needed for stimulus-bound eating somehow increase hunger. This possibility seems not to have been explored in a systematic manner, although a definite differentiation of self-stimulation with and without stimulus-bound drinking has been reported by Mogenson and Stevenson (1966).

However, there also may be a more behavioral (and "less physiological") factor at work in at least some of the self-deprivation studies. Consider the conditions in which the animals are placed: Two bars protrude from the wall at one end of the chamber, and a food cup is located on the wall at the other end of the box. Responses on one of the bars causes the delivery of brain stimulation, while responses on the other produces food. Why should some animals find it possible to break away from the bar that produces brain stimulation, to make some responses on the bar that produces food, and to leave the bars to gather their food pellets, while others ignore the food bar even though they are severely deprived? One possibility is suggested by the observation of Routtenberg and Lindy (1965), who noted that all their rats with electrodes in the septal area maintained adequate body weights by developing behavior patterns that allowed them to obtain both food and stimulation, while those with electrodes placed in hypothalamic regions were much less successful in breaking away from the ICS bar. At the very least, the behavior of the animals with electrodes in septal areas required a cessation of responses on one bar, and a shift to either the other bar or to the food cup. We know now that the purely behavioral consequences of hypothalamic stimulation make it unlikely that this interruption of self-stimulation will occur, whereas those of septal stimulation make such interruptions highly probable. When viewed closely, the typical immediate consequence of septal stimulation is seen to be a release of the bar and a pause, whereas the typical immediate consequence of hypothalamic stimulation is seen to be a repetition of the response with a very short latency. Indeed, animals with electrodes placed in hypothalamic regions frequently initiate one response while the stimulation from the preceding response is still being received, and only at high stimulation values does a post-stimulation pause appear (see Figure 15.15). This being the case, it is not surprising that some of the animals neglect the food bar. The hypothalamic ICS in these studies of self-starvation thus may simply be functioning as an extremely effective reinforcer, maintaining high rates of response and precluding other forms of activity, and it may actually have relatively little direct physiological effect on feeding "centers."

Further evidence of behavioral causes of self-starvation are found in experiments in which normal feeding is interfered with by prior activities. For example, rats placed in

activity wheels sometimes also show self-starvation behaviors, although the typical procedure in such studies provides each animal with a fixed period (such as 30 minutes a day) during which food is available and running in the wheel is prevented. Control animals given equal exposure to food, but no opportunity to run in the activity wheels, show normal maintenance of body weight. One of the possible explanations for the failure of experimental animals to eat as much food as the controls may also be applicable to the brain stimulation experiments: ". . . it may be possible that the reduction in food intake is brought about, in part, by a general heightened excitability, and that when the rat finally does have the opportunity to feed it is unable to eat efficiently because it is too excited" (Routtenberg & Kuznesof, 1967, p. 420). Rarely does one see a more excited laboratory rat than an animal which has had an electrode placed in the lateral hypothalamic areas, and which is stimulating itself under conditions of continuous reinforcement (that is, every response is reinforced with a brief train of stimulus pulses), and with the stimulus parameters adjusted to produce maximal rates. Routtenberg and Kuznesof

Figure 15.17. Mean number of responses emitted during 4 daily extinction tests. After 1000 reinforced bar presses, each rat was given four 15-minute extinction sessions. All animals were equally deprived. Note that the vertical axis is in log scale. (Culbertson, Kling, & Berkley, 1966.)

suggest that all forms of self-starvation are somehow related through the control of food-seeking behavior by the lateral hypothalamus, but it also seems possible that *any* reinforcer capable of maintaining extremely high response rates might have similar effects.

In contrast to the remarkable persistence subjects show during periods of stimulation is their relatively rapid cessation of responding when stimulation is no longer forthcoming (for example, Olds, 1955), or when the density of reinforcements is markedly reduced (Hodos, 1961). Of course, in most cases the comparisons of resistance to extinction have been between a reinforcer (food) with which the animal has had months or years of experience and brain stimulation with which he may have had only a few hours or days of experience. A typical result from such an experiment is shown in Figure 15.17. In this study, equal numbers of reinforced bar presses were allowed all animals. Some were reinforced for every such response, while others were on a fixed-ratio schedule in which every tenth bar press was reinforced. After 10 sessions of 100 reinforcements each, 4 daily 15-minute extinction periods were introduced. Clearly, the food-reinforced animals were more persistent during the extinction sessions than were those reinforced with electrical brain stimulation. Furthermore, the increased resistance to extinction engendered by utilizing a schedule of partial reinforcement had the same effect on the animals receiving brain stimulation as on those reinforced with food: As is frequently the case, the effect of the type of schedule seems to have a greater behavioral influence than the type of reinforcing stimulus.

Although it certainly is true that typical brain-stimulation procedures will produce low response persistence, there is some evidence that these effects are not inherent characteristics of brain stimulation reinforcement, but are—at least in part—artifacts of the techniques utilized in typical ICS experiments. For example, the onset of brain stimu-

lation usually is administered immediately upon the occurrence of the correct response; food, in contrast, almost always is obtained after a delay during which the animal approaches, seizes, and consumes the food. Following reinforcement, ICS animals are already in position to respond again; those receiving food can obtain reinforcement for their responses only if they leave the food dish and return to the place where responses can be made.
Thus, food-reinforcement procedures usually introduce at least a short delay of primary reinforcement and a short response-chain requirement, both of which are absent from most ICS procedures. That such differences might account for the lesser persistence of ICS-reinforced animals is suggested by the studies of Gibson, Reid, Sakai, and Porter (1965), Owens and Brown (1968), and Pliskoff and his associates (see, for example, Pliskoff & Hawkins, 1967). In these laboratories, brain stimulation has been delivered under conditions which require of the animals behaviors that mimic those commonly emitted by food-reinforced subjects. For example, Gibson and his coworkers reinforced lever pressing by presentation of a dry dipper, the licking of which then triggered the onset of the ICS. Under such conditions, lever pressing was as persistent as that observed when animals were reinforced with sucrose solutions, as measured in tests when only every twentieth response was reinforced, and during subsequent extinction tests. In the procedure used by Pliskoff and Hawkins, a two-unit behavioral chain was established: the animal was reinforced with brain stimulation every time he pressed Bar 2; this bar was withdrawn from his reach, but was presented again when he pressed Bar 1. Thus, responses on Bar 1 were reinforced by presentations of Bar 2, and responses on Bar 2 were reinforced with brain stimulation. In a typical experiment using this procedure, the requirement on Bar 1 might be some fixed ratio (such as, after every 10 responses, Bar 2 appears), or some other schedule of reinforcement might be imposed. Usually, Bar 2 was allowed to remain in the chamber until the animal had pressed it three times (and thus received three stimulations). Food controls have not been used, so the relative effects of this chained-response procedure and the multiple reinforcements on the persistence with which the subjects responded cannot be evaluated. However, it is clear that animals reinforced with brain stimulation in this manner do show considerable persistence (see Gandleman, Panksepp, & Trowill, 1968).

It also has become clear in recent years that such special treatment of ICS animals is not a prerequisite for persistence of responding, and more and more frequently one encounters research reports in which rats reinforced with brain stimulation are performing with about the same persistence as food-reinforced animals (see, for example, Keesey & Goldstein, 1968; Kling & Berkley, 1968). Why was such persistence not seen in the earlier studies of ICS? In addition to giving the animals relatively limited experience with this type of stimulus, experimenters also were quick to deliver a "free stimulation" whenever the animals paused. Such free stimulations would very rarely be given when food reinforcement is employed, but because satiation is not feared when ICS is utilized, and because the experimenter's hand switch is so easy to squeeze, the delivery of noncontingent stimulation was frequently utilized to keep ICS animals active during initial training and to hasten the emission of responses at the beginning of subsequent training sessions. This procedure probably reinforces such responses as not pressing the bar and thus tends to generate patterns of responding which actually compete with the "correct" one during extinction tests.

Another difference which distinguishes ICS from more typical reinforcers is the relative lack of satiation effects when ICS is employed. In some experiments, rats have been maintained for a day or more under conditions where they could stimulate themselves at any time (Olds, 1958b; Valenstein & Beer, 1964).

If electrodes are placed in hypothalamic regions (where the highest self-stimulation rates are usually found), a rat may self-stimulate more or less continually for the first 24 hours, then fall into exhausted sleep, and then return for bouts of self-stimulation.[19] Nothing akin to typical satiation is seen: The animal seems to stimulate himself until exhausted, and return to self-stimulation as soon as he is sufficiently rested to get back to work.

At one time, Olds (1958c) suggested that some regions might show satiation effects. For example, when the stimulating tips of the electrode were in the septal area, he found that the rate of self-stimulation declined after the first few hours, whereas if the electrode was placed in hypothalamic regions, the animals continued to stimulate themselves for very long periods of time, until it seemed that sheer exhaustion forced the animal to pause. However, recent studies of long-term response patterns in our laboratory suggest that these effects might be due to unintentional variations in the levels of stimulation applied to the septal and the hypothalamic areas. With typical preparations, the impedance of septal tissue is much higher than that of hypothalamic tissue, and thus, if equal voltages are delivered to the two areas, quite different current levels are produced. Animals stimulated in the septal area which show apparent satiation effects at low current levels seem to show more and more persistent responding as the current is increased, and current levels usually can be found where satiation seems not to occur. Further investigation of possible satiation effects is needed, with a relatively wide range of current levels and loci of stimulation as the independent variables.

In many other respects, it now appears that the reinforcing properties of electrical brain stimulation are no different from those of a typical reinforcer (such as food). For example, the rate with which a simple discrimination is acquired (Kling & Matsumiya, 1962; Sadowsky, 1969), the fineness of discrimination that can be established (Terman & Kling, 1968), and the breadth of stimulus generalization that follows discrimination training (see Figure 15.18 p. 656) all seem to be equivalent whether food or ICS reinforcements are used. In each of these situations, of course, it is the establishment of stimulus control that is observed, and in this domain, any one reinforcer may be the equivalent of any other.[20]

Finally, in some respects, ICS is distinctly superior to other reinforcement procedures, in that it can be delivered with more precise control over its parameters than can most other reinforcing stimuli. Thus, for the study of such problems as delay of reinforcement, ICS yields functional relations like those obtained with other reinforcers (Keesey, 1964a), and its convenience makes it the reinforcer of choice for parametric experiments. Similarly, when a reinforcer is needed which can be delivered at the discretion of the experimenter and without reliance on the responding of the subject, electrical brain stimulation provides the obvious solution. For example, precise temporal pairing of a neutral and a positive reinforcing stimulus in a study of conditioned reinforcement (Stein, 1958), or delivery of a positive reinforcer to a deeply curarized animal whenever a smooth muscle response occurs (Miller & Banuazizi, 1968; Miller, 1969) would be impossible with typical positive reinforcing stimuli, but is simple to engineer with ICS.

[19] The data of Valenstein and Beer suggest that the first orgy of responding and the subsequent exhaustion are followed by rhythmic changes in responding suggestive of a circadian rhythm. Prescott (1967) sampled self-stimulation rates at various points around the clock and also found evidence for such cyclic changes. His chamber contained two bars: Responses on the one were reinforced with brain stimulation, whereas responses on the other were never reinforced. Cyclic effects were seen only in the number of reinforced responses, leading Prescott to suggest that it was the reinforcement value of the brain stimulation, and not merely level of general activity, that was varying in a rhythmical fashion.

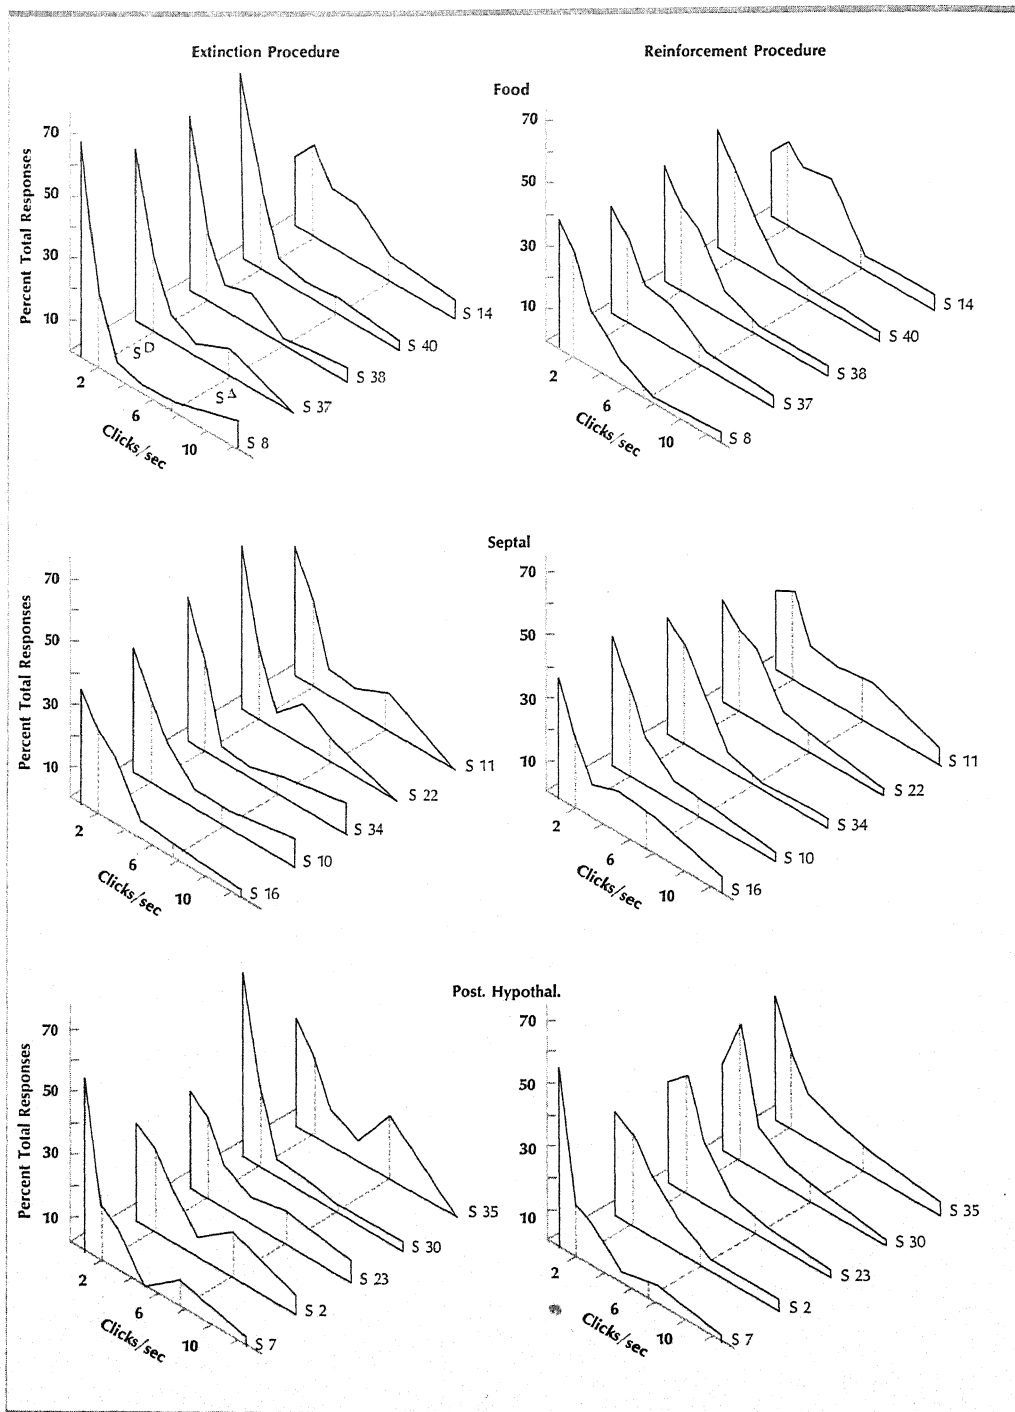
[20] Evidence contrary to this conclusion has recently been presented by Keesey and Lindholm (1969), who demonstrated that qualitatively different reinforcers produced consistent group differences in rate of learning a brightness discrimination.


Figure 15.18. During training, responses in the presence of the positive stimulus (S^D) of 2 clicks/sec were occasionally reinforced (variable interval 30 sec reinforcement schedule). Responses in the presence of the negative stimulus (S^Δ) of 7.8 clicks/sec were never reinforced. Training continued until re-

Why does ICS have reinforcing properties? The first attempts to answer this question reveal how little we really know about the phenomenon (phenomena?) called "reinforcement." A brief review of some of the attempts to understand "why ICS works" may help us gain a better perspective about the general problem of reinforcement, as well as a better appreciation of positively reinforcing brain stimulation.

ICS reduces drive level. If reinforcement were always accompanied by drive reduction, we might expect ICS to function through the same mechanism, except (perhaps) with greater rapidity and efficiency. How might such an effect be reflected? Perhaps the momentary level of excitement might be altered; after all, consummation of food-seeking responses eventually reduces activity, and ICS might have a similar quieting effect. However, mere observation of the animal stimulating himself shows that excitement and activity increase during the session, so a decrease in the overall drive level, or in the level of arousal, does not seem to account for the reinforcing effects.

ICS increases drive, excitement, or arousal. One of the chief weaknesses of the drive-reduction theory of reinforcement was its inability to provide a convincing explanation of why responding should be reinforced by conditions which must certainly increase drive level (for example, continued running to inaccessible food, observed by Schlosberg and Pratt, 1956). Perhaps it is drive *induction* that is common to reinforcers (Sheffield, 1966; see also p. 695), and that ICS is a technique for increasing excitement. How is drive or arousal level to be observed? One suggestion is to use some measure of the level of autonomic nervous system activity, such as heart rate. But stimulation at some electrode placements produces momentary heart rate *decreases*, although in other areas, heart rate *increases* are the immediate consequences of stimulation (Meyers, Valenstein, & Lacey, 1963; Perez-Cruet, Black, & Brady, 1963; Malmo, 1964). To the extent that heart rate reflects drive level, it seems that either an immediate increase *or* decrease in drive may accompany the brain stimulation, and thus such changes do not seem to offer an explanation for why ICS is positively reinforcing.

ICS stimulates a reinforcing network in the central nervous system. In various forms, this hypothesis has been suggested by Olds (see Olds & Olds, 1965). The basic theme that the reinforcing effects of ICS are, in at least some cases, attributable to the activation by the electrical stimulation of a neural system "whose activity serves to facilitate *ongoing* motor mechanisms and possibly to reinforce the firing of *antecedently active* motor systems" (page 381). When electrodes are so placed that they stimulate this system, the strongest possible positive reinforcing effects are found. To allow the hypothesis to account for other reinforcing effects, the reinforcing system is assumed to be spontaneously active and under the inhibitory control of input from "drive" centers. These latter centers are in turn under the control of two types of input: afferent stimulation associated with

---

sponse rates in S^D were at least 8 times the rates in S^Δ. The first generalization test was then given. Clicks were presented during 1-minute periods at a rate of 0.6, 2.0, 3.2, 5.2, 7.8, and 12.3 clicks/sec, each stimulus being given at least 9 times in a randomized order. On the first generalization test (Reinforcement Procedure), the variable interval reinforcement schedule was in effect whenever the S^D was present. In the second test (Extinction Procedure), responses never were reinforced. Between generalization tests, animals were retrained until the discrimination criterion again was attained. Each curve represents the behavior of one animal (identified by S number) on one of the two generalization tests. Results are grouped according to the reinforcing stimulus: food pellets, or electrical stimulation of the septal or of the posterior hypothalamic areas. Note that "peak shifts" (that is, higher response rates during 0.6 than during 2.0 click/sec periods) occur in all reinforcement groups, and that retraining and subsequent testing in extinction sharpen the generalization gradients but also increase response rates during S^Δ periods. (Kling & Berkley, 1968.)

activity of gustatory, olfactory, and visceral receptors, and direct stimulation of the drive centers by the chemical condition of the blood and other body fluids which bathe the cells of the centers. Thus, the smell and taste of food would inhibit drive-center activity, and thus (through inhibition of the inhibitor) increase the activity of the reinforcing system. Continued ingestion of food eventually would cause changes in the drive centers, producing increased inhibition of the reinforcing system and eventual cessation of eating and of food-reinforced responses. (How satiation effects with ICS would occur—if indeed they do—is not spelled out by the theory.)

Direct electrical stimulation of the afferent pathways feeding into the drive centers would have the same positive reinforcing effects that we might obtain through the "normal" presentation of food reinforcers, but the effects of such stimulation would be no more nor less effective than those obtained with food, whereas direct electrical stimulation of the reinforcing system itself would provide the greatest possible positive reinforcing effects.

A single reinforcing system under the inhibitory control of drive centers provides a means of visualizing the relations of normal reinforcers and electrical brain stimulation. By assuming that some positive loci act directly, and that others act indirectly to produce reinforcing effects, the major results of the brain mapping experiments are taken into account. Tentatively, the final reinforcing pathways are identified with systems present in the medial forebrain bundle-lateral hypothalamus complex, while the drive centers are given the suggested locus of the medial hypothalamus.

Whereas Olds and Olds (1965) postulate a single reinforcing system, Glickman and Schiff (1967) suggest the existence of sets of parallel neural pathways, each of which regulates a pattern of consummatory activity. Whatever stimulation activates such pathways, and the approach responses associated with them, would prove to be positive reinforcers, and whatever stimuli are present while these motor activities are in progress would become (by mere contiguity) capable of controlling these responses in the future.

ICS stimulates both motivating and reinforcing pathways. One form of this theory (Deutsch & Deutsch, 1966) assumes that every response must have some motivational basis for its first occurrence, and that it must have been reinforced if it recurs. Since ICS obviously can be used to establish and maintain responding in the absence of any of the more familiar procedures for instigating motivational conditions, it is assumed that the stimulation creates drive states directly by tapping into existing motivational pathways and at the same time causes responses to be reinforced by exciting existing reinforcement pathways.

A more elaborate form of this hypothesis has been proposed by Routtenberg (1968), who argues that septal and hypothalamic stimulation must have different substrates since their immediately elicited autonomic reactions (such as heart rate changes) and their interactions with aversive and with fear-provoking stimuli seem to be different. In the latter case, he points out that septal stimulation generally decreases the efficiency of the organism in avoidance or escape situations, while concurrent hypothalamic stimulation seems to increase escape or avoidance responding. He therefore suggests that septal stimulation may have its action through suppression of "Arousal System I," which he associates with the reticular formation, and to which he attributes drive properties. Arousal System I is dynamically related to Arousal System II, which he associates with the limbic system, and for which he postulates positive incentive properties. Thus, septal ICS would cause an immediate decrease in the activity of the drive system, and then compensatory increase in the activity of the positive incentive system. Hypothalamic ICS, on the other hand, is said to stimulate simultaneously both Systems I and II.

In Routtenberg's theory, the reinforcing effects of ICS would be attributed to the suppression of Arousal System I ("drive") by

the stimulation. Suppression of drive in turn permits the perseveration of the neural activity reflecting the behavior that led up to the onset of the reinforcer, and this perseveration is said to allow the consolidation of short-term memory. The suppression of Arousal System I is said to be a direct consequence of septal stimulation but only an indirect and delayed consequence of hypothalamic stimulation. Such hypothetical relations would seem to lead to the prediction that as a reinforcer, septal ICS would be superior to hypothalamic stimulation, but the available evidence (see p. 656) seems to suggest that the reinforcing (as distinct from the arousing) characteristics of these stimuli are all more or less the same.

Deutsch suggests that the rate of emission of responses reflects primarily the level of the ICS-produced drive, and he has employed responding during extinction as an index of the rate of decay of this drive (see Deutsch & Howarth, 1963). But as we have seen, the persistence of ICS-reinforced responding during both extinction and periods of low reinforcement density may be interpreted as reflections of the techniques used in training the animals and in delivering the reinforcers. A more direct mode of observing drive effects has been suggested by Quartermain and Webster (1968), who recorded general activity with a stabilimeter device during a one-hour period following reinforcement with water or with electrical brain stimulation. They found the ICS animals to be much more active at first, but to decline in activity over the 60 minutes to the same low level that the water reinforcement group had displayed throughout the entire hour. If general activity is accepted as a reflection of drive (and this is not always a defensible position; see Chapter 18), we might conclude that ICS animals do indeed show a marked drive decay following their last reinforcement. Since the electrode placements were ones which Routtenberg would expect to stimulate both drive and incentive systems, the activity data do not discriminate between the Deutsch and the Routtenberg viewpoints, but a repetition of the procedure, using septal stimulation, should elicit differential predictions from the theories, with Deutsch predicting no essential difference between the ICS loci, and Routtenberg predicting little or no arousal and subsequent drive decay with septal ICS.

In summary, these theories try to present a schema or a hypothetical organization for the nervous system, suggesting behavior-related functions and interrelations for known anatomical entities, and hypothesizing neurological centers or systems where the behavioral data seem to suggest that they may exist. At the present time, both the neurological and the behavioral data are too fragmentary to permit adequate evaluations of the suggestions that ICS has its effects through stimulation of one or two major systems which subserve such meaningful psychological functions as motivating and reinforcing behavior; indeed, it would be surprising if these rather heterogeneous phenomena proved to have unitary neurological substrates.

ICS stimulates pleasure centers. When one observes self-stimulation behavior for the first time, it is difficult to avoid the conclusion that something akin to stimulation of erogenous zones must be occurring. (Indeed, some wags referred to the self-stimulation procedure as "subcortical masturbation" when knowledge about the phenomenon was still very limited.) But such superficial impressions frequently are misleading: The animal appears to be oblivious to what is going on around him, but actually he can discriminate auditory stimuli even when these are presented only while he is actually receiving the electrical stimulation (Beer & Valenstein, 1960). Furthermore, the designation of this stimulation as "pleasurable" has no more basis than it does for any other event which proves to be a positive reinforcer. Certainly the verbal reports gathered in the studies in which humans (advanced cases of neurological or psychiatric disorders, where nothing else had helped . . .) have had stimulation applied to homologous brain areas have not helped understand the reinforcing effects of the stimulation. The statements are about as helpful as are those

obtained when a confirmed cigarette smoker is asked to describe how he feels when he inhales: reports mention that some patients say they like the stimulation or that it feels good (Sem-Jacobsen & Torkildsen, 1960), but no attempt has been made to collect all the statements, or to use the verbal reports otherwise in any systematic manner. This much at least can be said: not all reports refer to any one type of experience. Initially, there were suggestions that loci of positive stimulation might all be in areas subserving sexual behavior, and the occasional placement (for example, Herberg, 1963) that elicits seminal emission gave some support to these notions. However, such reactions are the exception rather than the rule, and clearly are not essential to the positive reinforcing effect.

Summary We are left with the same problem that existed before positively reinforcing electrical brain stimulation became a common tool of the behavioral laboratory: Why do some stimuli have positive reinforcing effects? We can eliminate any theories that hypothesize a single, positive-reinforcement neurological system, although it is more difficult to obtain critical evidence on hypothesized sets of systems that feed into a final common pathway (such as Miller's "go" hypothesis, 1963). We also can eliminate suggestions that any relations with unique endocrine or maintenance conditions are necessary for positive reinforcement, or that reinforcement always involves either arousal or relaxation.

Clearly, there is a need for thoughtful reanalysis of the problem(s) of reinforcement, and for a flexible posture on the part of the theorist.

SECONDARY REINFORCEMENT

Some events are reinforcing when first presented, while others seem to acquire reinforcing properties only after the organism has had certain experiences with them. Events falling into the first category have been called "primary reinforcers," while those of the second type have been called "secondary" or "conditioned" reinforcers. There is an unfortunate ambiguity to the term "secondary," but it has the advantage of neutrality, while "conditioned reinforcement" presumes that the process whereby reinforcing properties are acquired by previously neutral stimuli is that of classical conditioning. As we shall see, there are other interpretations of this phenomenon, and there may indeed be more than one process underlying the variety of acquired reinforcing effects. The term "secondary reinforcement" thus seems to be preferable, and we shall use it to label the phenomena considered in this section.

It is obvious that the reinforcing events which we use in everyday life ordinarily are not primary reinforcers, but rather they are reinforcers which are intimately related to specific past experiences and closely tied to the cultural and intellectual milieu of the individual. Indeed, the understanding and appreciation of the secondary reinforcers that are effective in social groups other than our own represents a major problem for teachers and politicians as well as for social scientists: approval and praise in the classroom may be a powerful reinforcing event for the child reared in a middle-class home, but many a teacher has found to her dismay that such is not always the case for children from markedly different backgrounds.

In psychological theory, secondary reinforcement has carried an unusually heavy burden. We find it involved in explanations of the establishment and maintenance of behaviors in everyday life where primary reinforcers seem to be absent; and we apply it liberally (and occasionally uncritically) when analyzing behavioral sequences observed in the laboratory. It therefore behooves us to examine the conditions under which the use of the concept is warranted, and to consider a few of the alternative interpretations that have been offered for the major phenomena usually explained by appeal to "secondary reinforcement."

How are we to identify the presence of secondary reinforcing effects? Perhaps the earliest procedure was the one used by Pavlov (1927, pp. 33–35) in his studies of higher-order conditioned reflexes. Pavlov described his procedure in these terms: "A dog has two primary alimentary conditioned stimuli firmly established, one to the sound of a metronome and the other to the buzzing of an electric bell. The appearance of a black square in the dog's line of vision is now used as yet a further stimulus, which is to be given the character of a secondary conditioned stimulus. The black square is held in front of the dog for ten seconds, and after an interval of fifteen seconds the metronome is sounded during 30 seconds." After 10 presentations of the square plus one or the other of the conditioned stimuli, salivation in response to the square had reached measurable proportions. However, "it was found impossible in the case of alimentary reflexes to press the secondary conditioned stimulus into our service to help us in the establishment of a new conditioned stimulus of the third order. Conditioned reflexes of the third order can however be obtained . . . in defense reactions such as that against stimulation of the skin by a strong electric current. But even in this case we cannot proceed further than a conditioned reflex of the third order" (pp. 33–34).

Note what had occurred: a previously neutral stimulus (black square) gained control of a response (saliva secretion) through "pairing" with other stimuli which themselves had at one time been neutral so far as control of salivation was concerned. Therefore, these other stimuli (metronome, bell) must have acquired some of the properties of the unconditioned stimulus (food), and thus they must have been not just conditioned stimuli but also "conditioned reinforcers." This, then, represents one way in which the secondary reinforcing properties of a stimulus may be evaluated: see if it can be used to establish a new stimulus as a conditioned stimulus.

A word of caution about the "pairing" of stimuli may be in order. Note that Pavlov specified that the black square was to be presented, withdrawn, and then (after an interval of many seconds) the metronome or bell was to be introduced. He found that if he presented the square and the metronome together, not only did the square never gain any control over saliva flow, but the metronome lost its conditioned stimulus properties.[21] Thus, "pairing" can have at least two effects: if the neutral stimulus is closely paired with a conditioned stimulus, both will become inhibitors of saliva secretion; while if the neutral stimulus precedes the conditioned stimulus by 10 seconds or more, it may acquire some of the properties of the conditioned stimulus.

Why do we refer to these experiments rather than to the more basic examples of Pavlovian conditioning? There seems to be at least one difference between what is conventionally called "secondary reinforcement" and the "mere" establishment of a previously neutral stimulus (such as a metronome) as a conditioned stimulus: the conditioned stimulus has acquired some of the properties of the food, so that the animal salivates, looks toward the food dish, and in other ways indicates that the metronome signals to him that food is about to be delivered. Still, there is nothing in this behavior that shows the metronome to have acquired any properties of a *reinforcer*. Such properties are, however, clearly demonstrated in conditioning of the second (or higher) order, and the distinction suggests one of the criteria we may use in deciding whether secondary reinforcing properties have indeed been acquired by a previously neutral stimulus: can a new stimulus be given control over a response by using the previously neutral stimulus as the reinforcer?

Although the Pavlovian procedure offered some of the earliest examples of secondary reinforcement, and indeed may represent the

[21] Pavlov called this phenomenon "conditioned inhibition," but remarked that it might better have been termed "differential inhibition." It is the former term, however, which has remained in use (see, for example, Maier, Seligman, & Solomon, 1969).

prototype of this phenomenon, the majority of the studies of secondary reinforcement have utilized not the classical, Pavlovian techniques, but instrumental (operant) procedures. Among situtations employing instrumental behavior techniques, the earliest demonstrations of secondary reinforcement examined the maze learning by rats when the final correct response was followed by entrance into a chamber in which the animal had, on other occasions, been fed repeatedly. In such experiments (see the summaries in Tolman, 1932) it was shown that presentation of food at the end of the maze produced the best performance, in terms of both speed and error elimination, but that performance did improve over trials when the only reinforcement at the end of the maze was entrance into a box that had on previous occasions been used as a place for feeding the animal. Such demonstrations were important in establishing the role of secondary reinforcement in maintaining long, complex chains of behavior in nonverbal organisms, but the very complexity of the maze situation, and the relatively low reliability of many of the early mazes,[22] led experimenters to seek other behavioral situations in which to analyze secondary reinforcing effects.

Indices of Secondary Reinforcement

Extinction tests A less complex test for the presence of secondary reinforcing effects is derived from the procedures used by Bugelski (1938) and Skinner (1938). In this test, the ability of the supposed secondary reinforcing event to maintain behavior during extinction is evaluated. Skinner trained a rat to press a bar, where each such response produced a loud click from the feeding

Figure 15.19. Effects of introducing a secondary reinforcing stimulus during extinction. During training, every bar press had produced both a click from the food-pellet dispensing mechanism and a food pellet. During the first portion of the extinction session, neither the food nor a click were presented. The curve shows the effects of this extinction procedure. At the arrow, the click (but not food) was reintroduced. (After Skinner, 1938.)

mechanism as a pellet of food was released into the food cup. After extensive training, the feeding mechanism was disconnected so that depressions of the bar produced neither food nor the noise of the mechanism. When this extinction procedure had lowered the rate of response almost to zero, Skinner reconnected the mechanism, but emptied it of food pellets. Now each press produced the mechanism noise, and the animal emitted a burst of responses. Such reappearance of vigorous and rapid responding (see Figure 15.19) typically is said to demonstrate the secondary reinforcing properties of the mechanism noise.[23]

Bugelski (1938) also observed the effects of feeding-mechanism sounds on responding during extinction, but he utilized separate groups of animals in his experiment. Each rat was trained to eat from the food cup whenever a pellet was delivered, and was then allowed 30 reinforced bar presses. Half the animals were then extinguished with neither pellet nor mechanism noise, while the other half had the characteristic noise occur after each bar press. The mean number of re-

[22] The reliability of a maze refers not to the apparatus itself, but to the behavioral measures resulting from its use. Thus, determining the reliability involves the same problems as determining the reliability of, for example, an intelligence test, with the additional problem that the behavior in which we are interested will be changing in systematic ways during maze "tests" whereas it will be relatively unchanged during intelligence tests. Maze reliability usually is estimated from the correlation of odd and even numbered trials (see Munn, 1950).

[23] These data were presented as evidence of the changes occurring in a behavioral chain when the stimuli for the next unit in the chain were eliminated. For that analysis, see Skinner (1938, pp. 103–104).

sponses emitted by the group extinguished in silence was 54, while the group extinguished with the mechanism noise present emitted, on the average, 78 responses. Again, this difference between the groups in this extinction test frequently is said to demonstrate the secondary reinforcing effects of the mechanism noise.

New response tests In the extinction tests described above, differences (either between groups or within a single organism) in the emission of a previously well-learned response are evaluated, but many factors in addition to secondary reinforcement might influence the rate at which that response occurs. For example, if the overall activity level of the animal were increased by the sound of the feeder, it is possible that many more responses would be emitted when the feeder mechanism noises were present than when they were absent. However, if the supposed secondary reinforcer could be used to train the subject to make a completely new response, one might be able to choose between the "arousal" and the "reinforcing" interpretations of the effects of the mechanism noises. Several variations of this procedure have been developed. For example, Skinner (1938) presented the feeder noise and food pellet 60 times (that is, he "magazine trained" the rats), and then inserted into the chamber a bar which, when depressed, produced only the feeder noise. The emission of responses during this test period was slow and irregular, but it was obvious that some appreciable conditioning of bar pressing occurred. Indeed, Skinner commented (p. 82) that the number of responses emitted was about the same as one might expect after 60 reinforced bar presses. Such potency of secondary reinforcers rarely is observed.

Another form of this test was employed by Clayton and Savin (1960). They trained rats to press a panel, and then introduced the contingencies: white noise-press-food; no noise-press-no food. Following this training, a bar was uncovered, and every depression of the bar by a rat in the experimental group produced a 5-second noise. Meanwhile, a control group with the same prior discrimination training received noise during the test session more or less at random, since each control animal was paired with an experimental animal and heard only the noises that were produced by the responses of the experimental animal. This "yoked control" design provides one form of control for the nonreinforcing but facilitating effects of a discriminative stimulus. The animals in the experimental group emitted more than twice as many responses as the controls during the test sessions, showing that the noise indeed had acquired secondary reinforcing properties which were over and above the effects due to mere activity arousal.

Choice tests A modified form of new response test utilizes a choice situation in which primary reinforcement is absent and the existence of secondary reinforcing properties is evaluated by observing whether stimuli previously paired with primary reinforcement are approached more frequently than control stimuli. A good example of this procedure is seen in the study by Saltzman (1949). Rats were trained to run from the start box of a straight alley to the goal box where food was placed. To provide distinctive stimulus conditions, half were trained to leap a hurdle into a black goal box, and half were trained to step down from the alley into a white goal box. They then were split into four groups. One group received 5 consecutive food-reinforced runs a day for 5 days, always with the same goal box. An intermittent reinforcement group had nonreinforced runs interspersed among the reinforced trials, but always with the same goal box. A differential reinforcement group received the same treatment as the previous group, but one goal box was always used for reinforced trials and one for nonreinforced trials. The fourth group received the same alley training as the first (consecutive reinforcement) group.

For the first three groups, the test for sec-

TABLE 15.3 MEAN NUMBER OF RESPONSES TO SIDE CONTAINING SECONDARY REINFORCING STIMULI DURING FIFTEEN TEST TRIALS.[a]

Group	*Experiment I*	*Experiment II*
Consecutive reinforcement	8.3	11.5
Alternate reinforcement	9.0	10.4
Differential reinforcement	10.7	11.6
Food reinforcement	10.0	—

[a]After Saltzman (1949).

ondary reinforcing effects took place in a U-shaped maze. Each animal had earlier been tested for his "preference" for a right or left turn in a similar apparatus, and now the non-preferred side of the U maze had attached to it the goal box in which food had been received during alley training. The other arm of the U terminated in the other goal box which, of course, had never been paired with food.

The fourth group had both ends of the U equipped with the previously nonreinforced goal box, and was given food for running to the nonpreferred side. In this way, they provided an estimate of U-maze learning with primary reinforcement only. The other groups never received food in the U maze; whatever preferences emerged would be attributable to the secondary reinforcing properties of the previous food-baited box (or possibly to the acquired punishing properties of the previously empty box). On each trial, the animal was detained in the goal box for 30 seconds. Fifteen spaced test trials were given.

The results are summarized in Table 15.3 under Experiment I. Note that the differential reinforcement group actually surpassed the food-control group in number of choices of the "correct" side. The consecutive reinforcement group, in spite of 25 reinforced runs to one of the goal boxes, showed only a small preference (compared to the "chance" value of 7.5 choices) for the goal box in which they had been fed. Saltzman suggested that this was the result of extinction of the secondary reinforcing properties of the goal box during the U-maze test, and that the other groups showed less extinction because they had been trained with partial reinforcement.

To test this hypothesis, he trained 3 more groups, using the procedures employed in Experiment I. This time, reinforced runs in the straight alley were interpolated among the U-maze tests with the expectation that this procedure would forestall extinction of the secondary reinforcing properties of the goal boxes (see "Maintenance Tests," below). As the results of Experiment II (Table 15.3) indicate, this procedure was an effective means of increasing the number of responses to the side of the U maze where the secondary reinforcing stimuli were located. More important, however, the results suggest that differential reinforcement may be no more effective than consecutive reinforcement in establishing secondary reinforcing properties. This issue will be considered shortly, but usually one would assume that the differential reinforcement procedure would produce discrimination of the goal boxes, and that a discriminative stimulus would be a stronger secondary reinforcer. Indeed, some psychologists assert that only a discriminative stimulus can be a secondary reinforcer—a conclusion quite at odds with Saltzman's results. Certainly these procedures deserve additional study, especially in other behavioral situations, to provide some estimate of their generality.

Maintenance tests As a means of maintaining the secondary reinforcing properties of a stimulus during tests of its efficacy, some experimenters intersperse among the tests occasional pairings of the to-be-tested stim-

ulus and the primary reinforcer. Collectively, these procedures are called "maintenance tests." Such testing and further strengthening of the secondary reinforcer may be carried out within the same situation, or may go on concurrently in two or more situations. A familiar example of the first type may be seen in most operant conditioning situations. If a bird has been magazine trained, the sound made by the operation of the food magazine, and the onset of the light which usually is placed within the magazine, serve as discriminative stimuli for cessation of ongoing responses and for approach to the feeder. When magazine training has become well established, the sounds and the light associated with operation of the food magazine can be shown to have reinforcing properties: if they are presented when some other response (a turn of the head, a peck at some spot on the wall, and so on) has just occurred, the likelihood that the response will be repeated is greatly increased. (At this point we have another example of the "new response" procedure, described above.) In a typical operant conditioning situation, of course, the magazine stimuli are always followed by access to food, so the secondary reinforcing properties of the stimuli presumably are continually renewed by this procedure.

Good examples of the concurrent variety of maintained testing procedures are provided by some of the studies conducted in the context of "token reward" investigations. For example, Wolfe (1936) and Cowles (1937) trained chimpanzees to insert poker chips into a vending machine from which bits of food were discharged. Once the operation of the "chimpomat" was mastered, the poker chips were used as reinforcers for other responses. Either immediately, or after considerable delay, the tokens thus earned could be inserted into the chimpomat and exchanged for food, thus maintaining the secondary reinforcing value of the tokens.

A valuable technique for investigating secondary reinforcement under conditions of maintained responding is provided by the chained reinforcement schedule (Ferster & Skinner, 1957). For example, a pigeon may be trained to peck a red response key, using intermittent food reinforcement to maintain a relatively constant response rate. Now suppose the key is made green, but when it is pecked, it turns red and further responses to the red key are reinforced according to the schedule previously in effect. Under these circumstances, responses to the green key are never directly reinforced with food presentations. Through the imaginative use of different numbers of units in the chain, or by utilizing different schedules of (secondary) reinforcement in various components of the chain, the relative contributions of frequency of primary reinforcement, length of the response chain, and the schedule of reinforcement itself have been investigated. A review of studies utilizing these maintenance procedures has been included in the survey prepared by Kelleher and Gollub (1962).

Yet another form of maintained response procedure utilizes concurrent reinforcement of two or more responses, at least one of which produces both the secondary reinforcing stimulus and a primary reinforcer. For example, J. Zimmerman (1963) equipped a rat chamber with two bars, one of which produced light and food when pressed, while the other produced only the light. The rat was free to operate either bar at any time. Responses on the "light-only" bar occurred with low but consistent rates for many weeks, with no obvious signs that the secondary reinforcing effects of the light were weakening. (For application of this strategy to the study of conditioned punishment, see Hake & Azrin, 1965).

Independent Variables

What are the major independent variables that influence the strength of secondary reinforcing stimuli? Since secondary reinforcing properties probably are established through classical conditioning and/or instrumental

learning, we might predict that any factors influencing these learning processes would also have parallel influences on secondary reinforcement. Tentatively, we may conclude that this indeed is the case, although there are many gaps in the available information.

Amount of primary reinforcement The secondary reinforcing strength of a stimulus as a function of the amount of primary reinforcer with which it is paired has been investigated in a number of experiments and the effects are remarkably similar to those obtained when amount of reinforcement is studied in other contexts. For example, if separate groups of animals are given different amounts of food when in the presence of the previously neutral stimulus, later tests of the secondary reinforcing properties of that stimulus may show little (Reynolds, Pavlik, & Goldstein, 1964) or no (Hopkins, 1955) effect of the different amounts of food. On the other hand, if each animal is exposed to more than one amount of food reinforcement (see discussion of shifts in reinforcers, pages 631–642), different degrees of secondary reinforcement correlated with different amounts of food can be demonstrated (for example, D'Amato, 1955b; Reynolds et al., 1964). Thus, differential training that allows each organism to be exposed to more than one condition of reinforcement again proves to be more effective than the absolute (single value) method of presenting the reinforcers.

Number of pairings Since the number of primary reinforcements is almost always a major factor in the initial stages of instrumental or classical conditioning, it is reasonable to assume that the number of times a previously neutral stimulus is paired with a primary reinforcer would determine, in part, the subsequent secondary reinforcing properties acquired by that stimulus. This seems to be the case, but the effect is not as large as one might expect. For example, Bersh (1951) and Miles (1956) used extinction tests to evaluate the secondary reinforcing properties of a light that had been paired with delivery of a food pellet whenever the rat pressed a bar. Separate groups of animals were allowed different numbers of reinforced responses and thus received different numbers of pairings of light and food.

When such a procedure is used, animals in the various groups will, of course, differ in the extent to which the bar pressing response has been established, and a subsequent extinction test may confound this response strength with the potency of the secondary reinforcing stimulus. Bersh attempted to equalize all groups for response strength prior to the secondary reinforcement test by introducing six 30-minute extinction sessions in which responses to the bar produced neither light nor food. At the end of the sixth session, all groups seemed more or less equal in response rate. Then, 3 test sessions were run, where each bar press produced the light, but no food. Small differences between groups, in the expected direction, were obtained.

Miles (1956) followed his training sessions with a typical extinction test of the secondary
Figure 15.20. Number of responses subjects made during extinction with and without secondary reinforcement. Each point represents the median number of responses emitted by each group during the extinction test. Animals receiving secondary reinforcement were presented both the light and the feeder noise whenever they pressed the bar. The remaining animals received neither stimulus during the test period. (After Miles, 1956.)

reinforcing properties of the light: half of each group was randomly selected and placed in the chamber where depressions of the bar produced the light and the noise of the feeding apparatus, while the other animals were run under identical conditions but with neither light nor noise following their responses. The results are shown in Figure 15.20. Note that the animals extinguished with the light and the click produced, on the average, more responses in extinction than those for whom the stimuli were omitted. These differences support the conclusion that the stimuli indeed did acquire secondary reinforcing properties. Note further that the difference between the two curves increases as the number of pairings in original training increases, suggesting that the strength of the secondary reinforcing stimuli is some positive function of the number of pairings during training. Finally, it should be noticed that, for *both* groups, the overall number of responses emitted during the extinction test is markedly influenced by the number of reinforcements in original training, thus confounding our interpretation of the main effects. It was this "contamination" which Bersh attempted to eliminate by his interpolated extinction sessions, and the results obtained by Miles demonstrate very nicely the type of interpretive problem which Bersh was trying to avoid. Miles recognized this problem, pointing out that his secondary reinforcers merely seemed "to contribute a constant proportion of the total number of extinction responses" (p. 129), with the average of the "no secondary reinforcement" group being approximately 80 percent of the "secondary reinforcement" at each of the values for number of pairings.

Do these results suggest that the number of pairings is a variable of little consequence? Such a conclusion seems to contradict common sense, and yet the studies in which each subject is exposed to but one condition of reinforcement quite consistently show that the number of pairings has a small effect, and even these may be artifacts of the strength at which the response itself was originally established. On the other hand, where more than one condition of reinforcement is given to each organism, the secondary reinforcing effects of stimuli clearly are influenced by the number of primary reinforcements. For example, Fantino and Herrnstein (1968) gave pigeons training in a 2-key box where responses on each key when they were illuminated with white light led eventually to a change in key color, the left to yellow, the right to red. Pecks during this link in the chain then were reinforced with food. Because the same reinforcement schedule was used when the keys were yellow and red, the rates of response emitted to yellow and red were the same. However, once in force, different numbers of food reinforcements were programmed before the key finally returned to the white condition. In this way, yellow could be given more pairings with food than red, and pecks on the white keys were used as the index of the secondary reinforcing properties acquired by yellow or red. It was found that the rate of response maintained by presentations of the colored keys increased as the number of primary reinforcements increased, up to a limit.

Again, these results remind us that many parameters of reinforcement may have significant behavioral consequences only when each subject is exposed to at least two conditions of reinforcement (see the discussion of amount of reinforcement on page 630).

Investigations of the effects of number of pairings in which the new-response test procedure has been used, support, in general, our previous conclusions. For example, Hall (1951a) gave each rat 25, 50, or 75 food-reinforced runs in a straight alley, and then gave 15 choice trials in a T maze. During this test, one of the goal boxes was that previously employed in the straight alley, and the other was a distinctly different box. Of course, no food was ever placed in the goal boxes during this test. Even the smallest number of pairings gave significantly more choices of the previously reinforced box than would be obtained by chance, and the larger numbers of pairings

gave larger proportions of appropriate choices. The differences between the groups, although significant, were relatively small, suggesting that the major effect of number of pairings may occur at some very low number, and that by the time we reach 25 or 50 pairings, the effects are essentially complete.

Effects of deprivation conditions There are several questions concerning relations of deprivation conditions to secondary reinforcement effects that have received fairly extensive study. The investigations of such problems are important because the fundamental nature of secondary reinforcement is not yet understood. One reasonable approach to take toward such problems is to see how manipulation of variables known to be important in other contexts influences the phenomenon in question.

In general, the deprivation conditions existing at the time secondary reinforcing properties are established, or at the time they are tested, appear to be of importance only in determining the basic level of the activity of the organism. For example, Brown (1956) gave half her rats 60 simultaneous pairings of light and buzzer with food pellet, while the other animals received the light and buzzer 28 seconds before a pellet was delivered, and thus presumably had no functional pairing of them. Half of each of these two groups received their training under relatively low food deprivation and half under fairly high deprivation conditions. In a second phase of the experiment, a small brass bar was inserted into the experimental box, and each animal was kept in his chamber until he had pressed the bar twenty times. For every press, the light and the buzzer (but no food) were presented. Half of the animals were tested under the same deprivation conditions used in their initial period of training, and half under the other condition, thus balancing out the effects of change per se in deprivation. Finally, each animal was placed in the box for an hour during which bar presses had no programmed consequences (that is, neither food pellets nor buzzer-light combinations were delivered at any time). Once again, each previous group was further subdivided into high and low deprivation subgroups. After the one-hour test, further bar presses resulted in the light and buzzer being presented, exactly as had been done in the original testing session.

The results of the experiment (and of a replication which introduced some modifications in the original procedure) were quite clear: pairings of the light and the buzzer with the food pellet did produce secondary reinforcing effects, as shown by the superiority of the experimental group in the 20-response test, and in extinction and retraining tests. However, in all these tests, the only effects of the deprivation conditions were to increase overall levels of responding, such that the relative differences between experimental and control animals remained the same at both high and low deprivation levels.

These results are similar to those of Hall (1951b), where deprivation differences at time of establishment of the secondary reinforcing properties were found to be insignificant, and those of Miles (1956) where differences in deprivation at time of testing were found to have proportionally similar effects on both experimental and control animals. Under such conditions, at least, we may tentatively conclude that deprivation level does not affect secondary reinforcing properties.

A somewhat different problem may be phrased as follows: If qualitative changes in deprivation conditions occur between the original time of pairing of stimuli and testing of the effectiveness of this pairing, will the secondary reinforcing properties of the stimuli diminish? The answer seems to be "yes," in much the same way that most other measures of behavior are detrimentally influenced by changes in the nature of deprivation conditions (D'Amato, 1955a; Wike & Barrientos, 1958). In these and similar studies, the conditions manipulated have been food and water deprivation. Although these indeed are the conditions about which we have the greatest amount of information, they are in a sense unfortunate choices, for they are so intimately

related. For example, rats deprived of water reduce their food intake by about one-half, while animals deprived of food similarly reduce their ingestion of water (see, for example, Verplank & Hayes, 1953; Grice & Davis, 1957). Consequently, the results of these experiments might be interpreted as evidence for either of two positions: (1) Secondary reinforcing properties of stimuli are uniquely associated with the deprivation conditions present at the time of the original pairing of the stimuli with the primary reinforcer, but that the rather extensive interactions between food and water deprivations provide the means whereby a partial transfer of secondary reinforcing properties across deprivation conditions might occur; or (2) Any change in the stimulus situation will, through generalization decrement, reduce the secondary reinforcing properties of the previously neutral stimuli. Although the latter hypothesis seems the more reasonable, the former cannot be rejected at this time.

A further relation between deprivation conditions and secondary reinforcing effects is revealed by studies of latent learning, and of the incentive characteristics of inaccessable foods or sham-fed substances. The earlier studies in this group were designed to test the hypothesis that substances which were "irrelevant" to the established deprivation conditions would be ignored by subjects, that they would neither be primary nor secondary reinforcers, and indeed, that subjects would learn nothing about such substances. In a typical experiment, Grice (1948b) trained rats in a T maze under conditions of water deprivation, with pieces of food so scattered around the water cup that the animals had to walk on the food to get to the water. Later, when shifted from water deprivation to food deprivation, the animals showed only chance success in going to the side of the T maze where food had previously been located. Apparently the chunks of food had no reinforcing effects when the animals were not deprived of food.

Similar results were obtained in a study of the reinforcing properties of inaccessable food (Schlosberg & Pratt, 1956). Three groups of rats were run in a T maze, with one arm of the T containing a dish of food that could be seen and smelled, but not reached, while the other arm was empty. One group was always tested when deprived of food for 23 hours; a second group was run under food deprivation conditions for the first half of the experiment, and then switched to the satiation condition; while the third group started under satiated conditions and then was made hungry for the last half of the experiment. Each daily session consisted of one free and one forced trial, to keep the number of responses to each side equal. The results indicate clearly that the conditions of deprivation determine whether the inaccessable food will serve as an effective reinforcer: the animals switched from satiation to food deprivation showed an increase in the proportion of free runs to the food side, while those that changed from deprivation to satiation went in the opposite direction. Surprisingly, the group maintained on food deprivation conditions continued to run to the inaccessable food on the free trials throughout the course of the experiment, showing no significant extinction effects during 24 sessions. The authors conclude that the daily feeding experiences of the animals outside of the experimental situation provided further pairings of the sight and smell of the food with ingestion, thus maintaining the secondary reinforcing properties of the inaccessable food.

Were the hypothesis proposed above correct, we might predict that maintaining animals on an all-liquid diet having a markedly different taste and smell from the laboratory food used in the goal box would result eventually in the loss of such reinforcing properties of the inaccessable food. Or, if male animals previously experienced in mating were never allowed to make contact with otherwise receptive females placed in the goal box, we should predict that the males would run less and less frequently to the side where the females were placed. Results of the latter type have been observed (see, for example, Kagan,

1955), but the former experiment seems not to have been done.

Also in this vein are the studies which suggest that the reinforcing effects of sham feeding may extinguish with time if not occasionally paired with the placement of food into the stomach (see, for example, Hull et al., 1951). An alternative interpretation of these results is that the sham feeding, as conducted in these experiments, has punishing effects, and that if these were eliminated, the species-specific reactions to foods would provide reinforcing effects which would not extinguish. Of course, if this were found to be the case, "secondary" reinforcement would be a distinct misnomer. (See the discussion of sham-feeding, pp. 620, 627.)

Effects of schedules of reinforcement One of the most potent variables the experimenter has at his disposal is the schedule of reinforcement, for by manipulating the schedule, he can modify the persistence with which a subject will respond and the pattern in which he responds. It is not surprising, therefore, that many investigations of secondary reinforcement should revolve around the schedule of primary reinforcement used during initial establishment of the secondary reinforcer, or around the schedule of presentations of the secondary reinforcer during tests of its efficacy. Wike (1966, pp. 427–428) has summarized a number of possible combinations of training and testing conditions, many of which have now been subjected to experimental analysis.

One of the most puzzling problems concerning secondary reinforcement is its apparent transience as it is studied in the laboratory. Inasmuch as intermittent reinforcement of a response rather consistently increases its resistance to extinction (see review by Lewis, 1960), it seems likely that intermittent pairing of the primary reinforcer with a neutral stimulus might produce a secondary reinforcer of greater persistence. This approach was taken by D. W. Zimmerman (1957), who used a buzzer as a signal preceeding presentation of water to water-deprived rats. Once the animals were making rapid approaches to the water when the buzzer sounded, he reduced the proportion of water presentations until (on the average) only 1 in 10 occurrences of the buzzer were followed by water. This procedure illustrates what is meant by "intermittency" during the training phase; Zimmerman also used intermittent procedures during his test of the utility of the buzzer as a reinforcer for a new response, bar pressing. During this test, the buzzer was presented for each of the first few bar presses, but thereafter only one bar press per minute was reinforced with the buzzer. The animals did show considerable persistence during the test sessions, but whether this was attributable to the intermittent pairing of the buzzer with water, or to the intermittent presentation of the buzzer during bar pressing remained unanswered.

A subsequent experiment by Fox and King (1961) included the control groups needed to answer these questions. They gave their rats initial training which consisted of 100 presentations of a small dipperful of sucrose solution, with each presentation of the dipper preceeded and accompanied by a buzzer sound. Half the animals received continuous reinforcement of the response of approaching the dipper when the buzzer sounded, while the other animals were trained with a gradually decreasing proportion of the buzzer trials on which the dipper was activated. In the end, this intermittent reinforcement group was receiving sucrose only after every tenth buzzer presentation and dipper approach. Overall, this initial training provided every rat with 100 buzzer-sucrose pairings, but in addition the animals in the intermittent group received an extra 100 buzzer presentations, which were not followed by sucrose.

For the test sessions, the animals were divided into 3 groups. A bar was inserted in the rats' box, and those in one group had the buzzer sounded whenever the bar was pressed; those in a second group had only one press per minute followed by the buzzer.

A third group, which never received presentations of the buzzer, provided a baseline against which to evaluate the possible secondary reinforcing effects of the buzzer. Animals in this no-buzzer control group made a significantly smaller number of responses than the others, showing that the training had indeed established the buzzer as a secondary reinforcer. Of the other animals, those trained and tested with intermittent reinforcement made the most responses during the test sessions, while the remaining groups were approximately equal in numbers of responses.

From these results, the investigators concluded that intermittent primary reinforcement produces increased resistance to extinction of secondary reinforcers only if the secondary reinforcer is intermittently presented during the test sessions. Furthermore, they also suggested that intermittent reinforcement during testing does not of itself contribute to increased resistance to extinction of secondary reinforcers.

There are, of course, many other ways to schedule the presentation of the primary and secondary reinforcers, and in light of the variety of behaviors generated by different reinforcement schedules, it would not be surprising if different forms of intermittency produced different results in tests of secondary reinforcement. In part, at least, this seems to be the case. For example, Stevenson and Reese (1962) compared the resistance to extinction of key pecking when half their pigeons had originally been trained with every tenth key peck reinforced with food, while the other animals had every peck reinforced. Each food presentation was accompanied by changes in the chamber light and the key light, and by the sound of the food hopper in operation. During the tests for secondary reinforcing effects of these stimuli, all food was eliminated from the hopper, and each training group was split into 3 groups for testing; one was provided no secondary reinforcement, another was provided secondary reinforcement for every tenth key peck, and the third was given secondary reinforcement for every peck. Their results indicate that intermittency during extinction testing increases the number of responses of birds trained with intermittent or with continuous reinforcement. Furthermore, from comparisons of each experimental group with the relevant control group that received no secondary reinforcement, they conclude that the most effective conditions are those in which the ratio of responses to reinforcements is higher in testing than in training.

Although these experiments lead to somewhat different conclusions concerning the effects of scheduling primary and secondary reinforcers, their results do agree in showing that secondary reinforcement effects are enhanced when intermittent scheduling is introduced. The differences between the studies probably should not be surprising, inasmuch as different reinforcement schedules, species, and test procedures were employed.

Valuable reviews of the effects of scheduling methods have been prepared by Kelleher (1966), by Kelleher and Gollub (1962), and by Wike (1966, especially pp. 427–436). Much of the original interest in scheduling revolved around the search for laboratory methods that might generate durable secondary reinforcers. But just suppose, suggests Wike (1966, p. 477) that it is the nature of all secondary reinforcers *not* to be durable: Would that not suggest a redirection of energies toward a study of conditions for best maintaining the efficacy of secondary reinforcers, possibly through frequent reconditioning and infrequent extinction tests? Of course, it probably never will be possible to conclude that secondary reinforcers are or are not durable, for durability is not an absolute quality. For laboratory study, however, intermittent schedules of primary and secondary reinforcement certainly increase the period over which the secondary reinforcers remain effective and allow us better opportunities to study their complexities.

What is the means through which intermittency increases the durability of secondary

reinforcers? One possibility is suggested by the observation of D. W. Zimmerman (1959) that the persistence of the very first responses in the behavior chain controlled by the secondary reinforcing stimulus seemed to be the crucial factor. He had trained rats to run from a start box through a short alley to a goal box where food pellets had been placed. Just before the start box door was opened, a buzzer was sounded. After this training, intermittent reinforcement was introduced, with some of the runs being made to an empty goal box. Next, a bar was inserted in the start box and a press on the bar turned on the buzzer and opened the start box door. From this time onward, no food was ever placed in the goal box, and yet the animals continued to press the bar and scamper out of the start box time after time. Over the course of 10 or more daily sessions, each rat emitted thousands of bar presses. Thus, the stimuli from the buzzer and from the door being opened not only had been shown capable of reinforcing a new response (bar pressing), but also were able to maintain this response with remarkable persistence. During the tests, running in the alley gradually extinguished; eventually, many of the rats ran no more than a few inches into the alley. When picked up and replaced in the start box, however, they repeated the process of pressing the bar and darting through the opening door. Because the rats continued pressing the bar only while their response to the buzzer remained vigorous, Zimmerman concluded that the secondary reinforcing properties of stimuli could be attributed to the ability of the stimuli to cause the next response in the response chain.

One serious limitation to the theory that the secondary reinforcer always elicits (or otherwise controls) a response which previously was instrumental in bringing about the primary reinforcing event is found in free operant studies of secondary reinforcement. In these situations, there rarely is any evidence that a response (for example, an incipient approach to the food tray) consistently is made following the presentation of a secondary reinforcer. For example, in the "chained schedule of reinforcement" procedure, a certain stimulus (such as a pattern of illumination on a pigeon's key) may always be present when pecks on the key finally are reinforced with food. Now a different pattern is projected on the key, and pecks in the presence of this second pattern eventually result in the reappearance of the first pattern. Observations of the response rates, and especially of the changes in the "local rates" immediately preceeding and following the presentations of the first pattern, are analyzed, and if the presentations of the first pattern have effects on key pecking similar to those to be expected if food had been presented, the first pattern is said to have secondary reinforcing properties.

The same logic as that used above can be applied to other types of reinforcement schedules (Kelleher, 1966). In all such situations it is clear that overt, incipient food-tray responses are not essential for the occurrence of secondary reinforcing effects. Of course, it could always be argued that prior training has extinguished the more gross features of such responses, but until some positive evidence is found that remnants of a response to a food tray are being made, it seems reasonable to conclude that the secondary reinforcing properties of stimuli are not uniquely associated with elicitation of the response which had been next in the original behavior chain.

Some problems of interpretation In almost every experiment in which secondary reinforcement is said to have been demonstrated, one or more alternative explanations for the results might have been offered. Overall, the reaction of most psychologists has been one of interest in these alternative hypotheses, but they persist in relying on the use of the secondary reinforcement concept. The main reasons for this reluctance to substitute other explanations probably lie in the facts that secondary reinforcement is an ubiquitous concept, whereas the alternatives tend to be relatively specific to a few sets of conditions, and that secondary reinforcement has an intuitive appeal, while some of the alternatives seem rather implausible from the point of view of common sense. A brief survey of some of the hypotheses will illustrate their major characteristics.

The "elicitation hypothesis" suggests that a previously neutral stimulus "merely" becomes a stimulus that elicits responses further along in the behavior chain. For example, if more responses are made during extinction when the "click" of the feeding mechanism is present than when extinction is tested in silence, is it possible that the click merely provides the stimuli in the presence of which the rat leaves the bar and approaches the cup? The rat whose pressing is greeted with silence does not receive the stimulus which controls leaving the bar, and so he stays there. In the past, of course, he has pressed only after returning from the food cup, so now he is less likely to make another response to the bar. This hypothesis sometimes has been attributed to Bugelski because he suggested (1956, p. 91 ff.) that secondary reinforcement need not be hypothesized to account for results like those found in his earlier (1938) study. Because Bugelski specifically disavowed any identification of his hypothesis with an interpretation based on a "discriminated stimulus" and leaned instead toward the view that the stimulus caused the subject to approach the cup, this interpretation has been called the "elicitation hypothesis." Yet the context in which he used the phrase "pattern of stimuli" when discussing the function of the feeder click suggests that the click might also be described as a discriminative stimulus for the next response in a previously established behavioral chain (see p. 672; and Zimmerman, 1959).

The "arousal hypothesis" suggests that a previously neutral stimulus arouses activity. There are two versions in which this hypothesis appears. In the first, the assumption is made that the area in which the subject is confined during the experiment is so restrictive of movements that any time his overall activity level increases, the response being measured (bar presses, for example) will of necessity increase. The second variation of the arousal hypothesis assumes that any increase in level of excitement or activity will give a proportional boost to all responses which the subject is likely to make in a given situation, and that if some response has been reinforced sufficiently often to become predominant, the introduction of the arousing stimulus will further increase the prepotency of that response. It is important to note that this hypothesis makes no assumptions about the temporal relations that must exist between the response and the arousing stimulus; hence, adequate controls may be obtained by noncontingent presentation of the stimulus to be tested for secondary reinforcing properties.

The "primary reinforcement" hypothesis argues that many supposedly neutral stimuli really are primary reinforcers, and hence are not really neutral. In many situations, it is possible to demonstrate the reinforcing effects of clicks, lights, snatches of song, momentary brightening of a TV picture tube, and countless other types of stimulation on the responses of birds, rodents, and primates of all varieties and ages. Because these effects cannot be attributed to prior pairing with other, known reinforcers, they must (by definition) be primary reinforcers.

Many of the "previously neutral" stimuli used in studies of secondary reinforcement are very similar to those mentioned above. An adequate control for the primary reinforcing value of the stimulus to be tested is afforded by a treatment that avoids any pairing of the stimulus with a known reinforcer and then presents the stimulus during the test session whenever the response occurs. The level of responding thus produced may be considered to indicate the primary reinforcing value of the supposedly neutral stimulus.

To some it may seem far fetched that the alternative explanations to secondary reinforcement described above can be given serious consideration. Yet we only need remind ourselves of the proven potency of "novel" stimuli as reinforcers to realize the need for incorporating appropriate controls in our experiments. Monkeys will respond with great persistence when the only reinforcer is an occasional chance to peek at the experimenter, an opportunity to manipulate gadgets, or other such "investigative behavior" (see review by Butler, 1965). Rats and mice will emit hundreds of responses when the only contingent event is a brief change in the illumination of their surroundings (see, for example, McCall, 1965). Similarly rats will run faster in an alleyway when the only modification of procedure is the introduction of a change in the patterns on the goal box walls (see, for example, Chapman & Levy, 1957). And humans—three months (Siqueland, 1970) of age, and possibly younger—are readily trained to make selected responses by the judicious use of visual or auditory stimuli. Thus, it is difficult to imagine a situation in which an investigator of secondary reinforcement could afford to ignore the potential primary reinforcing properties of his presumably neutral stimuli. (See reviews by Fowler, 1965, and Berlyne, 1967.)

Necessary and sufficient conditions for secondary reinforcement We have already noted that Pavlov observed the transfer of some of the properties of a conditioned stimulus to what was presumably a neutral stimulus when he presented the neutral

stimulus and then, after a pause, introduced the conditioned stimulus. It has frequently been suggested, (for example, by Kimble, 1961), that this "pairing" of stimuli may be the crucial operation in establishing a stimulus as a secondary reinforcer. In what has often been considered a crucial test of the classical conditioning hypothesis, Schoenfeld, Antonitis, and Bersh (1950) demonstrated that merely turning on a light for 1 second after the rat had started to eat his pellet did not generate any more reinforcing effect for the light than was obtained from the control procedure in which the animals saw no light during training. It is well to note that 4 daily 1-hour extinction sessions were given between training and the tests for secondary reinforcing effects, and although it is possible that this interpolated experience had no differential influence on the secondary reinforcing properties of the light, a direct evaluation of the effects of this extinction procedure seems never to have been made.

Nevertheless, the assumption has been that *if* mere pairing of light and food were a sufficient condition for the establishment of secondary reinforcing properties, the study of Schoenfeld, Antonitis, and Bersh should have been able to demonstrate such effects. At about the same time, Dinsmoor (1950) published the results of an experiment in which the discriminative and the secondary reinforcing effects of a light were found to be about equally effective in maintaining responding during an extinction test. These two studies from the Columbia University laboratory did much to sway opinion away from a "mere pairing" hypothesis, and toward the conclusion that, although pairing may be necessary, it is not a sufficient condition for establishing secondary reinforcing properties.

The suggestion that seemed most in harmony with the available data was that discriminative and reinforcing properties of stimuli are indeed distinct, but that a stimulus must acquire discriminative properties for some response before it can be a secondary reinforcer for any response (see, for example, Keller & Schoenfeld, 1950, pp. 236 ff.). This hypothesis has very specifically been limited to secondary reinforcers as observed in operant situations, and was not meant to be applied to Pavlovian "higher order conditioned stimuli." Yet even within this restriction, the present evidence suggests that, in principle, the hypothesis is wrong.

A crucial argument against the hypothesis is offered by an experiment in which mere pairing of a tone and a positive reinforcing stimulus proved sufficient to endow the tone with secondary reinforcing properties. Stein (1958) implanted chronic, bipolar electrodes in what he hoped would be positively reinforcing brain areas in 18 rats. After recovery from the surgery, each animal was allowed 6 1-hour sessions in a chamber containing 2 bars. Pressing one of the bars produced a 1-second tone; pressing the other bar had no programmed consequences. On the seventh to the tenth days, both bars were removed from the box, and each animal was given 100 pairings of tone and brain stimulation each
Figure 15.21. Mean number of responses for the 3 sessions before, and the 3 sessions after the tone had been paired with electrical brain stimulation. On the basis of a subsequent test of self-stimulation, the animals were divided into those which showed positive reinforcing effects of the stimulation and those which showed no such effect. (Stein, 1958.)

day. The next 3 days were test days for secondary reinforcing effects. Both bars were again placed in the chamber, and pressing the tone bar again caused delivery of a 1-second tone. Finally, to ascertain the effectiveness of the brain stimulation, each animal was given 1 hour in which he could stimulate his brain by pressing a lever.

The results are summarized in Figure 15.21. Note that the animals were split into two groups, depending on their reactions to the final, self-stimulation test. Thirteen were found to have clearly positive reactions to the electrical stimulation (self-stimulating 9 times a minute or more) whereas 5 made less than 1 response a minute and presumably had neutral or aversive reactions to the stimulation. Of those that were positively reinforced by the stimulation, the procedure of pairing tone and stimulation clearly produced secondary reinforcing effects for the tone, while such effects were absent for the nonpositive animals. Similar results under quite different conditions have been reported by Knott and Clayton (1966).

These are neither exceptionally strong effects, nor are they inevitably obtained (see Seward, Uyeda, & Olds, 1959; Mogenson, 1965). Furthermore, the fact that the experimenter has programmed a neutral and a positively reinforcing stimulus without requiring the subject to make a response before onset of the reinforcer does not insure that some response might not creep in and become established through the accidental contingency of the reinforcer and the response. Such "superstitious" behaviors (Morse & Skinner, 1957) in situations like the one employed by Stein (1958) have been observed (Pliskoff, Hawkins, & Wright, 1964), but they seem to be the exception rather than the rule. So we are left with the general conclusion that mere pairing of a stimulus with a reinforcer probably is a sufficient condition to establish the secondary reinforcing properties, although prior establishment of the stimulus as a discriminative stimulus usually will produce more persisting effects. (For a discussion of the problems superstitious behavior may present to the experimenter, see Herrnstein, 1966.)

Secondary reinforcing effects interpreted as information processes The hypothesis that a secondary reinforcing stimulus must have acquired discriminative stimulus properties implies that it also conveys information about the forthcoming appearance of the primary reinforcer, inasmuch as a discriminative stimulus gains control over a response through the correlations: discriminative stimulus-response-reinforcement; other stimulus set-response-nonreinforcement. Egger and Miller (1962) gave this supposition a more precise statement, namely, "a necessary condition for establishing any stimulus as a secondary reinforcer is that the stimulus provide information about the occurrence of primary reinforcement" and, if a situation includes more than one stimulus predicting primary
Figure 15.22. Stimulus arrangements used in studying information value and secondary reinforcement. Animals in both Groups A and B always received Stimulus 2 whenever a food pellet was delivered. For Group A, Stimulus 1-A was always given before, during, and after Stimulus 2; because Stimulus 2 never provided any information that was not already provided by Stimulus 1-A, it was said to be redundant and predicted to be low in secondary reinforcement value. For Group B, Stimulus 1-B also enveloped Stimulus 2, but because Stimulus 2 always preceded food pellet delivery while Stimulus 1-B sometimes occurred in the absence of food, Stimulus 2 provided information not carried by Stimulus 1-B and so was predicted to be the better secondary reinforcer. (After Egger & Miller, 1962.)

reinforcement, "the more informative stimulus will be the more effective secondary reinforcer" (p. 97). An "informative stimulus" was assumed to be one which predicted accurately that a response would be followed by a reinforcing stimulus, and which did not have its information value assimilated by some other stimulus. This latter characteristic is difficult to predict: It depends not just on degree of redundancy, but on attentional and perceptual factors. However, for purposes of the experiment, Egger and Miller assumed that a stimulus which always occurred within the temporal bounds of another stimulus (see Figure 15.22) should acquire little or no secondary reinforcing strength because its information value would be assimilated.

Two groups of rats were trained to press a bar under conditions in which every fourth press caused a pellet of food to be dropped into a nearby food cup. The bar was then removed from the chamber, and for the next 5 days, each animal was exposed to presentations of a flashing light, a tone, and food. Animals in Group A always had a 2-second presentation of Stimulus 1 (for example, the light) completely overlapping every 1.5-second presentation of Stimulus 2 (for example, the tone); both of these stimuli overlapped the delivery of the food pellet. The animals in Group B received exactly the same treatment except that they had extra presentations of Stimulus 1 aperiodically interspersed amongst the other stimuli. In other words, Stimulus 1 was not completely reliable as a predictor of food for Group B, while Stimulus 2 was always a dependable indicator that food was coming. For Group A, Stimulus 2 was redundant, carrying no information not already given by Stimulus 1. Over-all, Stimulus 1 was followed by food all of the time for Group A and 55 percent of the time for Group B; Stimulus 2 was always followed by food for both groups.

After the fifth day of presenting stimuli, the bars were reinserted in the chambers; every animal was allowed a short period of food-reinforced responding, and then a 10-minute extinction period (no food, no stimuli) followed. As soon as the 10 minutes had passed, a 25-minute test period was begun, during which the stimulus to be tested for secondary reinforcing effects was delivered for 1 second after every third bar press. The next day, exactly the same procedure was repeated, except the other stimulus was tested. Half the animals were tested first with Stimulus 1, and half with Stimulus 2; half of each group had flashing light for Stimulus 1 and tone for Stimulus 2, and half had the opposite arrangement.

TABLE 15.4 MEAN NUMBER OF RESPONSES DURING TWO 25-MINUTE SESSIONS OF SECONDARY REINFORCEMENT TESTING.[a]

	Reinforcing stimulus	
Group	*Stimulus 1*	*Stimulus 2*
A	115.1	65.8
B	76.1	82.6

[a] After Egger & Miller (1962).

The results (see Table 15.4) indicate that a stimulus which cannot be used as a dependable predictor of food (such as Stimulus 1-B) is a less potent secondary reinforcer than the more dependable predictor (Stimulus 1-A). Furthermore, the results suggest that "enclosing" a stimulus within the temporal bounds of another stimulus (as Stimulus 2 is encompassed by Stimulus 1 for Group A) reduces the secondary reinforcing effects that the enveloped stimulus can acquire.

Such results do not necessarily weaken the discriminative-stimulus hypothesis, for the extent to which a stimulus gains control over bar pressing would supposedly be influenced by the same factors that influence its "information value." Nor do they negate our tentative conclusion that merely pairing stimuli is a sufficient condition for establishing secondary reinforcing effects. Indeed, Egger and Miller (1963) noted in a subsequent experiment that a simple pairing of a stimulus with food produced secondary reinforcing effects as strong as those acquired by a stimulus specifically positioned to gain maximum information value.

Recent studies (Ayres, 1966; Seligman,

1966) in which the Egger-Miller hypothesis has been tested in conditioned suppression situations have found that redundant stimuli do acquire significant new properties. In the conditioned suppression procedure (see pp. 712–717), a steady baseline of behavior is first established, usually by providing intermittent positive reinforcement to the subject. Then a neutral stimulus is paired with an aversive stimulus (such as electric shock), and the extent to which the baseline behavior is suppressed when the previously neutral stimulus is presented is used as an index of acquired aversiveness. Clearly, redundant stimuli do acquire such properties, although "informative" stimuli may be even more effective. Such results would seem to place severe restrictions on the Egger-Miller hypothesis, at least as it currently is formulated.

For some considerations of the applicability of secondary reinforcement to complex problems of human behavior, see Skinner's (1953) discussion of "generalized reinforcers" and Hill's (1968) survey of the uses made of the concept of secondary reinforcement by various theorists.

DELAY OF REINFORCEMENT

"Delay of reinforcement" is a term that refers to the interval of time between the occurrence of a response and the delivery of its reinforcing stimulus. In each situation some criterion must be set which will define the moment of occurrence of the response. Where simple locomotor responses in an alleyway are studied, the moment the subject enters the goal box (as measured by depression of a movable floor or by interruption of a photocell beam) is usually taken as "the" instant that the instrumental response occurs, even though the movements involved are much the same as others which had been emitted earlier. In other cases, specification of the "correct" response may be quite simple: Movement of a bar or key sufficient to close a switch defines the response, and in discrimination situations it is only necessary to add the requirement that such switch closures occur in the presence of certain stimulus conditions.

All of the experiments which properly belong in this section employ instrumental (Thorndikian, operant) procedures. There is no strictly analogous operation in classical (Pavlovian, respondent) conditioning, although the temporal intervals between the conditioned and the unconditioned stimulus, or between the conditioned stimulus and the occurrence of the response, are sometimes said to be akin to delay of reinforcement. There are two reasons why it does not seem proper to include in the same category the manipulation of temporal factors in the classical and the operant procedures: (1) The hallmark of classical conditioning is the delivery of two stimuli (the conditioned and the unconditioned stimuli) without regard to the behavior of the organism, while the crucial interval in the procedure involving a delay of reinforcement is that which occurs between the execution of the response and the presentation of a reinforcing stimulus. "Reinforcement" in the classical situation means the paired presentation of the conditioned and the unconditioned stimuli, and the onset of the latter usually is timed with respect to the former, and not with regard to any characteristic of the response in the situation. Thus, in the usual sense, there can be no "delay of reinforcement" in the classical conditioning situation. (2) The generally different form of the functional relations obtained in operant and in classical situations, when these temporal factors are varied, increases our suspicions that these are quite different problems. In operant situations, the effect of delay of reinforcement is always to slow acquisition; in classical conditioning situations, there is some temporal interval between the onsets of the conditioned and unconditioned stimuli which is optimal in each situation, and the most rapid acquisition is never obtained if there is no delay between the onsets of these two stimuli. Thus, it is clear that delay of reinforcement is a problem peculiar to operant situations.

There appear to be two major effects of

imposing delays of reinforcement during original training: acquisition is retarded, while subsequent retention *may be* enhanced. The effects on acquisition have received the greater amount of attention from experimenters, and there is rather good agreement among studies that utilized quite diverse procedures. At the empirical level, at least, these effects of delay of reinforcement can be said to be "well understood." In contrast, studies of the effects of delayed reinforcement during retention tests have been less consistent in their findings, although some patterns are beginning to emerge from the many experiments that have been reported in the last decade. Although both types of problem sometimes have been investigated within the same experiment, we shall consider the problems as if they were quite separate.

Acquisition as a Function of Delay of Reinforcement

The roots of this problem reach back to the earliest systematic studies of simple learning in the American laboratories. Thorndike's first experiments (1898, 1911) led him to an appreciation of the role of the reinforcing stimulus in simple learning, which he summarized in his Law of Effect[24] (see also p. 690). Watson (1917) reasoned that a crucial test of the Law of Effect could be obtained by placing a delay interval between the occurrence of the correct response and the occurrence of the "satisfying state of affairs." He conducted an experiment in which laboratory rats were required to dig through sawdust to obtain entry into a compartment from which they could reach a food container. Half of the animals were allowed to eat as soon as they reached the food; the other half found a perforated lid on top of the food cup, and were not allowed access to the food until 30 seconds after they had reached the cup.[25] The "correct response" was, in Watson's analysis, the complex act of digging through the sawdust and finding the opening into the enclosure. If Thorndike were correct in his identification of the "satisfying state of affairs" as the crucial factor in "stamping in" the correct response, the occurrence of a great many other acts between the correct response and the attainment of the food by the delay group should impede their acquisition of the task. At least, so reasoned Watson, and when he found the two groups to be similar in their acquisition of the digging response, he concluded that the Law of Effect must be invalid.

Other investigators (Simmons, 1924; Warden & Haas, 1927; Hamilton, 1929; Roberts, 1930) developed less complex behavioral situations in which "the correct response" could be specified more easily than in Watson's problem box. During this time, the T maze gradually replaced the older, multiple-unit maze as the apparatus of choice in many laboratories. When applied to the problem of delay of reinforcement, the T maze allowed the experimenter to obtain both time scores and error scores in a relatively simple situation in which the time interval between the correct turn at the choice point and food reinforcement could be manipulated quite easily. Hamilton (nee Haas) concluded that the relative lack of effect of delay that she and Warden had obtained in their earlier (1927) study might have been a result of delaying the delivery of food by holding the animal in the goal box, where cues associated with prior feedings were no doubt available to him. She therefore introduced into the T maze a set of compartments through which the animal had to pass to reach the goal box. When separate groups of animals were delayed from 0 seconds to 7 minutes in such compartments, de-

[24] Thorndike's early statement of the Law of Effect emphasized the "stamping in" of stimulus-response connections when the response was followed by a "satisfying state of affairs," and a "stamping out" when an "annoying state of affairs" followed the response. "Satisfiers" and "annoyers" were defined behaviorally as that which the animal would approach and with which he would maximize contact or that which he would avoid and with which he would minimize contact.

[25] We now know that the inaccessible food probably was immediately effective as a reinforcer. See the discussion of the experiment by Schlosberg and Pratt (1956) on page 669.

creased proficiency was found for all the delay groups. Wolfe (1934) utilized the same technique in studying the acquisition of a black-white discrimination, where the animal had to turn sometimes to the right, and sometimes to the left. Here the effects of delays were even more marked, yet some learning occurred even when delays as long as 20 minutes were imposed.

The fact that delaying the animal briefly in the delay compartments hindered learning was no great surprise, but that the rat could learn *anything* when a delay of several minutes was imposed suggested to some theorists (for example, Tolman, 1932, p. 43) that all animals, regardless of the length of the delay, knew equally well where the food was to be found but that the delayed presentation of food merely decreased the "demand" for the food. Others (Hull, 1932, p. 140) concluded that forms of reinforcement other than those provided by the food itself must have been present in the apparatus, and especially in the delay compartments from which the animal was allowed to escape directly to food. A test of this hypothesis seemed to require the elimination of both the delay compartments and a goal box in which feeding always occurs. Perin (1943) adapted the apparatus devised by Skinner (1938) for the study of this problem. He placed his rat in a cubical enclosure into which a small bar could be inserted. If, in his movements in the vicinity of the bar, the animal happened to depress it sufficiently to close a silent switch, a food pellet was dropped into a cup within reach of the animal. Separate groups of animals were trained, either being given reinforcement immediately or after delays of 2, 5, 10, or 30 seconds between depression of the bar and delivery of the pellet. Immediately after the bar was depressed, Perin withdrew it from the chamber. Thus, for animals receiving delays in the delivery of food, there was no possibility that subsequent bar-pressing responses might possibly be made just as the pellet finally arrived. This procedure precludes the use of error scores or response rates, but is well suited to the measurement of the time required for the animal to press the bar after it has been presented. All groups showed orderly changes in this latency during training; the most rapid decrease across trials occurred in the immediate reinforcement group, while a less rapid decrease occurred for the groups delayed 2, 5, or 10 seconds. However, the 30-second delay group showed a consistent *increase* in latency across trials, suggesting that they were learning to make some response other than depression of the bar when it was presented.

Based largely on the results obtained by Perin, Hull (1943) suggested that delays longer than 30 seconds would probably result in no learning of "the" reinforced response, and that those improvements in performance that were observed following the longer delays in earlier experiments, probably were a result of immediate secondary reinforcement augmenting the delayed primary reinforcement. Spence (1947) pushed this line of reasoning one step further: he suggested that wherever learning occurs with delay of reinforcement, there must be immediate "secondary reinforcement" present.

It is easy to imagine that stimuli in the delay compartments of a T maze might acquire secondary (or conditioned) reinforcing properties, for they are consistently followed by entry into the goal box and eating. But what might the source of such secondary reinforcement be in Perin's apparatus, in which the animal always was within the same enclosure? Here, all of the stimuli from the apparatus would seem to be associated both with occasional feeding and with more frequent periods of nonreinforcement. Spence (1947) and Grice (1948a) suggested that the stimuli resulting from the animal's own pressing the bar might be one class of stimuli which consistently precede feeding and which thus might acquire reinforcing properties. Were this the case, an experiment in which no one response consistently preceded reinforcement might eliminate even this last set of potential secondary reinforcing stimuli and thus test
Figure 15.23. Learning curves for each of the 6 groups trained with various delays of reinforcement. The number of trials required to reach 75 percent correct was used to construct the gradient in Figure 15.24. (After Grice, 1948a.)

Spence's hypothesis that no learning at all would occur if even the slightest delay were imposed between the correct response and the delivery of the reinforcing stimulus. To test this hypothesis, Grice (1948a) utilized a black-white discrimination with the correct response requiring a left turn on some trials and a right turn on others. Separate groups of rats were delayed from 0.5 to 10.0 seconds
Figure 15.24. Rate of learning as a function of delay of reinforcement. The reciprocal × 1000 of the number of trials to reach the level of 75 percent correct choices is plotted against the time delay. Experimental values are represented by black dots and the smooth curve is fitted to these data. (After Grice, 1948a.)

with the control group receiving immediate reinforcement. The average rate of improvement was inversely related to the length of the interval, and most animals in the 10-second group never reached the performance criterion. The more important finding, however, was the very marked effect of even so short a delay as 0.5 seconds. The average learning curve for each of the groups is shown in Figure 15.23; the number of trials required to reach the 75 percent correct point in training provides the points through which the gradient in Figure 15.24 is drawn.

If all sources of secondary reinforcement had been eliminated, this gradient should have dropped to zero as soon as any delay was introduced. That it did not suggests that some further sources of secondary reinforcement were present. For example, some differential response patterns may have been developed as animals ran through the area where the discriminative stimuli were displayed. Thus, a rat fed shortly after running through a white compartment might come to make eating responses when he later comes to white areas again (see p. 621). These "fractional antedating goal reactions" (Hull, 1952) usually are assumed to have stimulus consequences, and thus these response-produced stimuli could, through their pairing with eating, become the immediate secondary reinforcing stimuli that might be needed to "explain" Grice's results. Fortunately, this cumbersome hypothesis does not seem necessary because Grice's results can be replicated in situations using electrical brain stimulation as the reinforcer (see, for example, Keesey, 1964a; Culbertson, 1970), where the subject makes no overt consummatory responses and the "antedating goal reaction" hypothesis seems superfluous. Furthermore, about the same delay-of-reinforcement gradient is found with delayed brain stimulation as with food reinforcement (Keesey, 1964a). These facts suggest the existence of some finite period during which prior responses can be reinforced without a chain of behavior to

bridge the time interval (that is, a "pure" delay of reinforcement process).[26]

For the most part, interpretations of delayed reinforcement effects have clustered around two viewpoints which, for convenience, may be called "motivational" and "associational." As we have noted, Tolman (1932) was an early proponent of the motivational point of view, and in a broad sense, the position to which Spence (1956) came was quite similar, for both assumed that delayed reinforcement reduced the incentive value of the reinforcing stimuli.

"Associational" interpretations are so named because they assume that delayed reinforcement primarily affects what the organism learns to do—and almost all psychologists believe that "learning" is an associational process. Hull's (1943) assumption that the stimulus-response unit received smaller increments in habit strength from delayed than from immediate reinforcement is one example of the associative viewpoint (see also Capaldi, 1967). A quite different variety of associational interpretation is seen in the analysis of delayed reinforcement effects given by Skinner (1938). No spread of reinforcing effects to responses occurring prior to the reinforced response is assumed; whatever response is occurring at the moment the reinforcing stimulus appears is made more likely to reoccur; but prior responses (such as "the correct response" in a delayed reinforcement experiment) can increase in probability of reoccurrence if they are part of a chain of responses of which the reinforced response is the last unit.

This latter interpretation affords a very reasonable explanation for such phenomena as the response patterns which emerge after exposure to a fixed ratio reinforcement schedule (where every *n*th response is reinforced). Reinforcement is "delayed" in the sense that the early responses are themselves not reinforced. However, in the initial training sessions individual responses are usually reinforced, and the first imposition of a ratio requirement usually involves so small an increase in the required number of responses between reinforcements that the ratio is emitted without any great pauses between responses, so that one of the responses is soon reinforced. As the ratio requirement is increased, the same process is repeated, so that we might think of the response class being reinforced as "respond after responding." When reinforcement does occur, it is this response unit that is immediately reinforced, and not just the last member of the chain.

The response chains in such scheduled reinforcement procedures usually are homogeneous, and the similarity of the responses early in the chain to the response actually reinforced makes secondary reinforcement a plausible explanation for the persistence of responses far removed in time from the reinforced response. By contrast, if heterogeneous response chains are involved, it usually is necessary to train the subject to make the last (that is, the reinforced) response first, and then build the chain toward the first response.[27] In this process, it is assumed that each response produces stimuli which are both the discriminative stimuli for the next response, and the secondary reinforcing stimuli for the prior response, thus "explaining" how responding can continue to exist in strength when reinforcement is delayed to the end of the chain. This assumption is consistent with widely accepted notions of secondary reinforcement, and the fact that new responses can be added to the distal end of the chain is independent evidence that the response more proximal to the reinforced

[26]The results also remind us that even the rat can retain information over a period of a few seconds and suggest that this admirable little creature may be quite comparable to man in holding information about cues and responses in his "short-term memory."

[27]Although this backward order of training organisms to make heterogeneous chains of responses is the only "sensible" procedure from the point of view of contemporary reinforcement theory, it should be realized that systematic comparisons with other procedures (such as starting training with the first response in the chain) seem not to have been published.

response does indeed produce secondary reinforcing effects.

The same reasoning that is applied to the persistence of response chains also is frequently offered as an explanation for the acquisition of responses in delayed reinforcement situations. We mentioned above Spence's (1947) hypothesis that secondary reinforcing stimuli are produced by the responses which occur consistently prior to reinforcement, which is basically the same interpretation as that just discussed for heterogeneous and homogeneous chaining.
Figure 15.25. A typical animal chamber arranged for 2-choice discrimination problems. On the further wall are 2 response keys and a panel light used to indicate that the next trial may be initiated. Trials begin when the animal breaks the light beam falling on the photocell at the end of the chamber, thus insuring that he always is at least that far from the response keys at the start of each trial. Bars or panels may be substituted for the response keys, and a food cup or liquid dipper may be inserted if those reinforcers are to be used. In this illustration, the animal is connected by chronically implanted electrodes, a flexible lead, and an overhead swivel to a circuit that provides electrical stimulation of the brain.

To illustrate the problems involved in unraveling behavior in such delayed reinforcement situations, and to see how the hypothesis that proposes that secondary reinforcement is response-produced might be applied, let us trace the sequence of events in a typical delayed reinforcement discrimination experiment (Culbertson, 1970). The major features of the animal's chamber are shown in Figure 15.25.[28] Through a sequence of pretraining procedures the animal has been taught to run to the rear of the chamber whenever the center panel light is turned on. A light beam is located at the rear of the chamber which, when broken by the animal, causes the center panel light to go out and the key lights to be illuminated. If the "correct" (for example, the brighter) key is pressed, the chamber is immediately darkened, and the reinforcement is then delivered after the appropriate delay interval. Pressing the incorrect key produces an immediate blackout, but no reinforcement. Following a fixed period of darkness, the sequence again begins when the center panel light is turned on. In this manner, the start of each trial is under the control of the animal. Therefore, some indication of the incentive value of the reinforcing conditions may be obtained from the rate at which the animal sets up the trials by going to the rear of the chamber, and the speed with which he runs from there to the keys when they are illuminated. The speeds of these

[28] In this case, reinforcement is provided by electrical stimulation of the brain, delivered to the electrode through the flexible cable from the swivel mounted on the chamber roof. The insertion of a dipper or food cup adapts such chambers for use with liquid or solid foods. Electrical brain stimulation is especially convenient for delay of reinforcement experiments, for the delay interval can be controlled quite precisely, and a true zero-delay condition can be included in the design. However, the same general problems of analysis exist for all types of reinforcing stimuli.
Figure 15.26. The average choice speeds for each of 6 different groups trained with various delays of reinforcement. The break in the curves occurs between Day 1 and Day 2 of the training procedure. Choice speed was measured from the moment the discriminative stimuli appeared on the response keys until the animal displaced one of the keys. (From Culbertson, 1968.)

responses typically are inversely related to the duration of the delay intervals. A set of such data from Culbertson's (1968) experiment is shown in Figure 15.26.

What are the specific responses that are learned by animals in the delayed reinforcement groups? We might imagine a trial on which an animal presses the correct key, turns to his left, and rears up on his hind legs; if, at that moment, reinforcement is delivered, it is this last response (rearing) which the subject will most likely make again, not the pressing of the key in the presence of the positive discriminative stimulus. Of course, reinforcement of such "incorrect" responses as rearing occurs because the delay interval had been initiated by the correct response, and this same sequence of responses might be (adventitiously) reinforced a few times and thus become more and more frequent. Some animals do indeed show such "superstitious" conditioning (Skinner, 1948), but the majority of animals in delayed reinforcement studies do not show any recognizable, regular pattern of behavior during the delay interval, nor do the most rapid learners show any greater incidence of superstitious behavior than the slower learners. Clearly, bridging the time gap with an overt response chain is not essential to successful performance in discrimination situations utilizing delayed reinforcement. But suppose we deliberately reinforced a chain of responses such as *press the brighter key, turn to the left,* and *stand up.* Would such an animal show the typical delay of reinforcement effects? Almost certainly, the answer

would be "no," for in this case the onset of the reinforcer is contingent not upon the passage of a certain amount of time, but upon completion of a specific sequence of responses. Moreover, reinforcement of that last response is given immediately. Thus this is not a delayed reinforcement situation but one of immediate reinforcement of a short heterogeneous response chain, and the behavior generated would be appropriate to these conditions.

If we do not determine the responses to be emitted, but instead allow each organism the opportunity to develop its own sequence by introducing gradually increasing delay periods after initial training with immediate reinforcement, the response may continue with unabated persistence and accuracy (Ferster, 1953; Dews, 1960). In this way, organisms can "adapt to" gradually increasing delays. However, if even brief delays of a few seconds are suddenly introduced, marked deterioration of behavior results (for example, Skinner, 1938).

These observations suggest that it is the absence of a regularly reinforced response or a sequence of responses which is at least in part responsible for the slow acquisition and low response rates characteristically obtained with delayed reinforcement conditions (Grice, 1948a, pp. 10–11). At the same time, it also seems that learning can occur with brief delays in the absence of such "mediating" response chains, and that the presence of overt, easily recognizable "superstitious" response chains in delayed reinforcement situations is no guarantee of superior performance. Indeed, the relatively motionless organism may have developed a pattern of responses that is just as efficient as the sequence which is more easily observed by the experimenter![29]

[29]We do not wish to preclude the possibility that delay intervals may be bridged by "observing behavior" in which the organism attends to sequences of stimuli or by other activities that do not necessarily involve measurable responses. However, at the present there is a distinct lack of evidence for such mechanisms in delayed reinforcement situations.

Effects of Delay of Reinforcement on Response Persistence

Delay of reinforcement retards learning. But if the response is once learned, will the delay conditions present during training have any influence on subsequent behavior? For example, would training with delayed reinforcement have systematic effects on retention, response variability, or resistance to extinction? Surprisingly few aspects of behavior have been examined in this context; the majority of studies have focused on the relation between delayed reinforcement and subsequent resistance to extinction. The reason for this interest is understandable: Extinction behavior is very much prolonged if reinforcement is occasionally omitted during training, and if delayed reinforcements are on a continuum running from immediate reinforcement to infinitely long delays (that is, omission of reinforcement), then training with delayed reinforcement should increase resistance to extinction.

To investigate this possibility, a frequently used experimental design has assigned subjects to separate groups and trained each group with a different delay of reinforcement before introducing the extinction test. However, this design introduces a familiar dilemma: If equal amounts of training have been given all groups, their proficiency at the end of training will be negatively correlated with the durations of delays with which they were trained, and if they do not start extinction with the same proficiency, relative resistance to extinction cannot be evaluated. On the other hand, if a "constant effect" strategy is followed, that is, if every subject is allowed to continue training until all have reached the same proficiency, the unequal amounts of training will produce different degrees of resistance to extinction and thus preclude an unambiguous test of the effects of delayed reinforcement.

Two means of circumventing this dilemma have been devised. In one, the initial training

with delayed reinforcement has been followed by a period during which all animals were given immediate reinforcement; then the extinction procedure is introduced (see, for example, Sgro & Weinstock, 1963). Even after this training, the groups may enter the extinction period at different levels of proficiency, making it difficult to evaluate the effects of omission of reinforcement. As an alternative procedure, we might allow sufficient training for all groups to reach the same level of proficiency before extinction is introduced. Where this method has been employed (see Sgro, Dyal, & Anastasio, 1967; Culbertson, 1968) no differences in resistance to extinction appear. Apparently the extra training necessary to allow the groups trained with delayed reinforcement to catch up to those trained with immediate reinforcement eliminates whatever differences might result from the similarity of training and extinction conditions for the subjects trained with delayed reinforcement.

The most obvious way to design a study to investigate the effects of delayed reinforcement on resistance to extinction is to assign each subject to a specific delay and conduct all of his training with this fixed delay interval. As we have seen, this type of experiment does not yield consistent evidence that delay of reinforcement increases resistance to extinction. An alternative design was suggested by the hypothesis that partial reinforcement increases resistance to extinction because the subject cannot discriminate training from extinction conditions. If this hypothesis is correct, and if delayed reinforcement is on a continuum with extinction, then partial delay of reinforcement during training should also make the transition to extinction conditions difficult to discriminate and thus increase persistence of responding during extinction periods. This reasoning was tested by Crum, Brown, and Bitterman (1951) in a study in which one group of rats always received immediate food reinforcement at the end of a short alley, while another group received immediate reinforcement on half the trials and received the food after a 30-second delay in the goal box on the other trials. The 50-percent delay group ran significantly faster during extinction than the subjects that were immediately reinforced, thus confirming the original prediction. Similar results have been reported for both simple locomotor responses (see, for example, Scott & Wike, 1956) and for discrimination learning (Kintsch & Wike, 1957). However, several other experiments using similar procedures have not shown any significant increase in resistance to extinction that can be attributed to delayed reinforcement during training (see, for example, Wike & Kintsch, 1959; Wike & Remple, 1959). A review of the relevant literature led Renner (1964) to conclude that delays of 30 seconds or more probably were necessary if an increase in resistance to extinction is to be seen. Almost certainly such values would depend upon the situation in which they are applied, and we should not assume that 30 seconds represents a delay of special significance for behavior. Indeed, as we point out below, at least one relevant study (Pubols, 1958) found no further difference in extinction behavior once delays as long as 4 seconds had been introduced. At present, it does not seem possible to give a clear description of the variables which are crucial in producing enhanced resistance to extinction through manipulation of delay of reinforcement.

It is possible, of course, that the enhanced resistance to extinction is a function of the variability introduced into the training conditions by partial delay of reinforcement, for variability per se could also make more difficult the discrimination of a transition from training to extinction. Variable delayed reinforcement (as contrasted with partial delayed reinforcement procedures) has been examined in several experiments, again with inconsistent results. For example, Wike and Kintsch (1959) postponed the presentation of the reinforcer for 10, 20, or 30 seconds, in a random order, thus enhancing the unpredicta-

ble nature of the training situation. They found no increased resistance to extinction from this procedure, whereas Logan, Beier, and Kinkaid (1956) found that varying delay of reinforcement between 1 and 30 seconds did increase resistance to extinction. This literature is confounded by the great variety of procedures employed during pretraining, training, and extinction, and no clear picture has yet emerged from the welter of results. Certainly it is not safe to conclude that either delay per se, or the variability introduced by partial or varied delay procedures, will increase resistance to extinction.

Resistance to reversal training has also been used as an index of response persistence. Here the typical design involves training on an initial discrimination, with different groups of animals receiving different reinforcement conditions. The discrimination is then reversed, so that responses to what had been the positive stimulus are now nonreinforced; the animal continues in extinction until the first response is made to the formerly negative stimulus, when reinforcement is delivered. Pubols (1958) trained animals in a simple position discrimination, using delays of 2, 4, 8, or 16 seconds; the same delays were used during reversal training, with some animals from each of the original groups being assigned to each of the reversal groups. The results indicate that the most rapid reversal was made by animals trained with the shortest delay of reinforcement (2 seconds). A greater number of responses to the formerly correct side before the first reversal, and subsequent slower learning of the reversed discrimination problem, was found for all groups trained with the longer delays of reinforcement. There have been some failures to confirm this where slightly different procedures have been used (see Renner, 1965a,b), and it is not clear why delayed reinforcement influences resistance to reversal of discrimination in only some experiments.

Perhaps the requirement by Pubols of a specific response to escape from the delay compartment and gain access to the goal box was a crucial feature of the procedure, for this represents one way in which the procedure could have generated quite different behaviors in the animals delayed for only 2 seconds and those delayed 4 seconds or more. The delay interval was timed from the moment the animals entered the delay chamber, and at the end of the interval the door leading to the goal box was unlocked but not opened. It then was left to the rat to push his way into the goal box. Two seconds probably represents the minimum delay interval that could be handled with reliability in such a situation, and probably did little more than force a break in the locomotion of the rat. Delays of 4 or more seconds might easily provide opportunities for distinctive behaviors to occur and be reinforced, and these might later provide a source of secondary reinforcement during extinction. These speculations are suggested by the fact that neither enhanced resistance to extinction nor increased perseveration of responding to the formerly correct stimulus was found after training with delayed brain stimulation reinforcement (Culbertson, 1968). Use of this reinforcer not only allows the inclusion of a true zero delay baseline group, but it also allows the reinforcer to be delivered at the end of programmed delay intervals without requiring any special response of the animal and without allowing uncontrolled intervals to be added to the end of the delay as a function of the behavior of the animal on that trial. That no enhancement is found when delays of brain stimulation reinforcement are programmed suggests the reasonable conclusion that delay per se may have no effects on resistance to extinction but that the responses which occur during delays may be capable of modifying subsequent response persistence. The importance of the responses which occur immediately after the criterional response (the one on which reinforcement is contingent, and which initiates the delay interval) is emphasized also by the studies which manipulate knowledge of results and other forms of informational feedback.

Delayed Knowledge of Results

At first glance, it might appear self-evident that knowledge of the accuracy of our responses should be reinforcing, and that delays in presentation of this knowledge (or "informational feedback") would have the effects now so well documented in delayed reinforcement experiments. That the situations are not exactly the same was first suggested after a considerable number of experiments failed to reveal any significant effects of delayed knowledge of results on acquisition of such skills as target pursuit, or on verbal rote learning tasks like paired associate learning.

Two general classes of procedure seem to be subsumed under the general heading of "delayed knowledge of results." In the first case, the major (and sometimes, the only) source of information about the accuracy of each response is controlled by the experimenter, with some subjects being given immediate feedback while others receive the information after various delays. For example, a subject may be given lessons on a musical instrument and the auditory feedback delayed for a few tenths of a second. If he has not had extensive experience with this instrument, or if it is one which requires continuous auditory monitoring of the output (such as the violin) the information about the adequacy of each response which can come through nonauditory channels (such as visual, tactual, or kinesthetic) is minimal. Under these conditions, novices show limited or no improvement with practice, and subjects with considerable experience frequently find the situation so disturbing that they refuse to continue the experiment (Smith, 1966). The effects may be even more marked than those produced by delayed feedback of one's own voice, where it is possible for some subjects to speak "without listening" and thus avoid the disruptive influences of the feedback (see Waters, 1968).

In contrast to the very marked effects of delayed informational feedback when the experimenter has control over most or all of the sources of feedback, minimal or no effects of delayed knowledge are found when such skills as lever positioning or target pursuit are studied (see I. McD. Bilodeau, 1966). In these cases, there is some information immediately available about the response just made, and subjects seem to be quite capable of holding such information for several seconds until told how well the response met the requirements.

Holding such information until knowledge of results is given becomes even more efficient when both the stimuli and the responses can be described in words. For example, Brackbill and her colleagues have studied the effects of delayed knowledge of results in several situations, all of which have a definite stimulus display and a response which is clearly defined for the subject. In one such procedure (see, for example, Brackbill, Adams, & Reaney, 1967), children were told that they would be shown pairs of pictures and that they must tell the experimenter which one of each pair they thought was "the correct one." Two major findings emerge from these studies: Delayed knowledge of results, even up to 30 seconds, has relatively little effect on the number of errors made during learning; and subsequent tests of relearning indicate that delayed knowledge facilitates retention.

A major distinction between such procedures and the ones employed in the traditional delayed reinforcement studies seems to lie in the definition given to the situation by the experimenter. Here the child is told that one of each pair of stimuli is correct; he is told how he is to indicate his choice; and the experiment does not proceed until knowledge of results has been given. In delayed reinforcement experiments, on the other hand, everything is done to avoid defining the moment of occurrence of the response, and the question of major interest is the effect of subsequent presentation of the reinforcer when behavior has continued to flow on past the response chosen by the experimenter as the one from which he will begin to time the

delay interval (the "correct" response). Such situations seem to be more frequent in everyday life than ones in which we pause after a response and await knowledge of its adequacy. The two types of situations seem to raise some rather different problems for behavioral analysis.

The facilitative effects of delayed knowledge of results on retention has usually been found where subjects are allowed to correct their errors before proceeding to the next trial, and where they are free to make continued responses to the stimuli during the delay interval. In this way, the amount of practice with the stimuli, and the adequacy of the verbal descriptions of them, may vary between immediately informed subjects and those in the delay groups. But whatever prove to be the reasons for the improved retention, the educational consequences seem clear: Programmed instructional devices should allow the interval between response and feedback to be adjusted, for the best interval almost certainly would be different for various types of material and levels of proficiency.

In summary, it would seem that delayed knowledge of results involves qualitatively different processes than those encountered in delayed reinforcement, and that we probably should reserve the latter term for situations in which the subject is not given specific information beforehand as to which of his responses will be the critical one. For those cases, "delayed knowledge of results" or "delayed informational feedback" seem to be equally suitable terms.

Delayed Reinforcement and Mediating Responses

Delays of reinforcement are, of course, of trivial importance if a human subject can verbalize the important characteristics of the situation and later reinstate the essential features through the use of language. Certainly, if adult humans were to be given the simple tasks required of rats or pigeons in some of the studies just reviewed, it would be surprising if they did not perform perfectly even under longer delay conditions. Everyday life presents us with far more subtle discriminations than those used in our experiments, but the principles involved seem to be the same: Where language or other differential responses do not continue through the delay period, acquisition is greatly impaired by even slight delays of reinforcement. As might be expected, young children can tolerate longer delays than completely nonverbal organisms, but children are significantly hindered by delay intervals (such as 30 seconds) which adults would probably find quite inconsequential (Hockman & Lipsitt, 1961).

If verbalizations can extend the duration of the stimulus-response relation until reinforcement arrives, why would delayed reinforcement ever influence adult human behavior? At least three types of situation fall outside our ability to use language in this manner. In the first place, there are countless situations in which we lack the experience to identify and label the significant features of the discriminative stimuli, of our responses, or both. The craftsman sees distinctions and tunes his responses in ways that are beyond the apprentice, but as experience and guidance are provided, these deficiencies may be overcome. In the second, we might not have the necessary talent to apply differential labels to stimuli or responses, often because of sensory deficiencies or low intelligence. Finally, there are failures to apply labels that are usually attributed to the "unconscious" nature of the situation. In general, "unconscious" means that one has no way to speak of or think about a situation or an experience. This inability may represent a lack of a vocabulary to label the experience, or it may be a consequence of the types of motivated forgetting called "repression" by Freud. In either case, the absence of appropriate language removes the major advantage man has over other organisms when coping with delayed reinforcement situations.

While verbal devices allow the most subtle

distinctions to be coded and the most information to be carried across delay intervals, other forms of "mediating responses" (see pp. 779–789) are also employed in similar capacities. We have seen that the opportunity for distinctively different response patterns during the delay interval allows learning to proceed at much more rapid rates than when such response patterns are precluded (see, for example, Grice, 1948a). Postural mediating responses may also be used to "bridge the time gap" in *delayed reaction* experiments, where the interval is placed between the termination of the discriminative stimuli and the earliest instant at which the responses to these stimuli may be emitted (see pp. 786–789). Human adults find little challenge in waiting a minute or so before making a response, *if* the situation can be given appropriate verbal description. Indeed, if told to appear at a certain place in 6 months, most of us could delay our reactions for that period and then respond appropriately. Notes written in appointment books or on calendars are devices used to reinstate the appropriate stimuli when the delay interval has passed. Some appreciation of the value of words as mediating responses can be gained by comparing our success in the face of such lengthy delays with the performance limits shown by organisms which have no such language tools. For example, toddlers who have not yet gained the ability to describe the experimental situation in words may be unable to solve delayed reaction problems which require delays of half a minute. On the other hand, non-human primates such as chimpanzees and macaque monkeys have performed at high levels of accuracy with delays of 5 minutes or more (Tinklepaugh, 1928; Yerkes & Yerkes, 1928). Such observations remind us that language is not essential to solve problems involving temporal delays, but words surely are the most versatile mediating responses and their use frees man of much (but by no means all) of the detrimental influences of delays of reinforcement and delayed reaction situations.

SUMMARY

The Common Properties of Reinforcers

A problem of persisting interest for more than 75 years has been the nature of the physiological and/or structural changes in the nervous system that underlie behavior modifications. In some way, the effects of experience must be coded, stored, and retrieved; and whatever theories are proposed to account for these processes must be in harmony with the facts of behavior as revealed by careful, systematic study in the laboratory. Of course, many of the pioneering theories of the neuronal basis of experience assumed that a single set of processes could account for all the observed behavioral effects of experience, and the apparently rich variety of behavioral changes were seen merely as elaborations of one basic type of "learning." Pavlov (1927, p. 395), for example, asserted that "it is obvious that the different kinds of habits based on training, education and discipline of any sort are nothing but a long chain of conditioned reflexes." He thus felt that the theory of activity of the cerebral hemispheres which was being developed to account for his observations of conditioning would be applicable to the full range of effects of experience. The view that conditioned reflexes were the basis of all experience also was adopted enthusiastically by Watson (for example, 1919), although the difficulties in applying the model based on conditioned reflexes to some of the newly developed experimental techniques (for example, double alternation) led many psychologists to doubt the adequacy of proposing that any single mechanism is responsible for all varieties of learned behavioral changes.

In the last few decades there has been even less confidence in the hypothesis that all the effects of experience are basically of one type. Hull (1943) had remarked that proposing that more than one mechanism was responsible for changes in behavior would seem to be a violation of the principle of

parsimony, yet he cautioned his readers that such "seeming improvidence in biological economy . . . is not without parallel in other fields; most organisms possess more than one means of excretion, and some organisms possess more than one independent means of reproduction" (p. 82). Such speculations aside, it is clear that if we restrict our considerations to the operations[30] by which behavior modifications can be effected, we can identify not one but several procedures, which appear to be basically different: classical conditioning, operant training, pseudoconditioning, sensitization, habituation, perceptual (or "exposure") learning, and possibly others. In light of these observations, it would seem wise to adopt a flexible position regarding the number of mechanisms whereby behavior is modified.

If we restrict our attention to modifications of operant behavior, we find that there have been numerous attempts to suggest a single common property for all instances of positive reinforcement. Usually these suggestions have been called "theories of reinforcement"; several representative viewpoints were considered in our discussion of reinforcing brain stimulation (pp. 642–660). In the present context, it may be useful to note that some of these suggestions can be tested directly, whereas others can be evaluated by indirect tests only.

As an example of the hypotheses that can be directly tested, we may cite Thorndike's (1911) well-known conclusion that "satisfiers" (that is, positive reinforcers) all share the property of being stimuli which the organism will approach and with which the organism will maximize contact. A more-recent example of a hypothesis that can be tested directly is Premack's (for example, 1965) suggestion that all reinforced responses share the property of being of lower probability than the reinforcing responses which are contingent upon them.[31] Because the common properties suggested in connection with the Thorndike and Premack views are behavioral, we need only make the appropriate observations of the behavior of subjects in a variety of situations to evaluate the hypotheses. In the strictest sense, a single clear exception to such generalizations would be sufficient to disprove (or disconfirm) them, but in actual practice the exceptions which we can suggest are themselves subject to a variety of interpretations. For example, Thorndike's definition of "satisfier" can be unambiguously applied to situations in which there is a definite consummatory response (such as eating), the duration of which may be measured; but "approach" and "maintain contact" have no clear referents when reinforcement involves such operations as presenting signs of approval, knowledge of results, or brief sensory changes, for in such cases we are left without overt consummatory responses which might be counted or timed. Indeed, in the case of sensory change, it is the brevity and discontinuity of the presentations which frequently seem to be the most important determinants of the reinforcing effects,[32] and if the subject were to maintain contact with the reinforcers, their effectiveness soon would be lost. Similar problems of interpretation arise in connection with Premack's hypothesis, where the crucial issue becomes the determination of the relative probability of the reinforced and the reinforcing responses.

Perhaps the best known of the theories of reinforcement which required indirect tests was the Hull-Miller drive- (or drive-stimulus) reduction hypothesis (see, for example, Hull, 1943; Miller, 1957; see also Miller, 1963). In the absence of any objective criterion of drive reduction, critics of the theory set out to test it by demonstrating the effectiveness of reinforcers which (from a common sense point of view) would not reduce drive and which might even create an increase in drive. Among the best-known studies of this type were the

[30]See pp. 554–594.

[31]See pages 623–624 for a more precise statement and a further consideration of this hypothesis.

[32]A review of stimulus-change reinforcement has been published by Kish (1966).

demonstrations by Sheffield and his students that copulation without ejaculation (Sheffield, Wulff, & Backer, 1951) or ingestion of saccharin, which cannot be metabolized (Sheffield & Roby, 1950), would reinforce instrumental behavior. A review of these and other experiments may be found in Sheffield (1966).

When we consider even the most superficial surveys of reinforcers, the great variety of events which prove to be reinforcers immediately suggests that any property which would be common to all would indeed have to be extremely general. At this time, no such property is known, with the exception of the defining property itself. That is, the only thing which reinforcers have in common is that they have been found to increase the probability of occurrence of the reinforced response. This is not the kind of common property which theorists debated so vigorously a decade or two ago, when "crucial" experiments testing the validity of drive-reduction (and other) theories were frequent features of psychological journals. Furthermore, even this property (as we shall see) requires rather elaborate qualification when we attempt to discuss it apart from the conditions of the specific experiments in which the reinforcers gain their labels.

That "reinforcer" and "reinforcement" are concepts developed by students of behavior to help them think about observed facts of behavior is rather obvious, but we sometimes seem to forget that the emergence of a useful concept does not necessarily prove the existence of a parallel process at the samê or at other levels of analysis. For example, there is at this time no evidence for a single physiological process paralleling what we call "reinforcement," nor is there any compelling reason to believe that there is but a single psychological process subsumed under our concept of reinforcement. The limited conceptual status of "reinforcement" may be more readily appreciated if we consider next some of the restrictions which must be observed in utilizing the concept.

Contingency of response and reinforcer Although we frequently speak of "reinforcing stimulus" or "reinforcing event," such terms are only convenient shorthand expressions for a more adequate description, which always would include a description of (1) the response on which the reinforcer is contingent, (2) the reinforcer and the conditions under which it is applied, and (3) the behavioral measure from which the increase in probability of response was estimated.

Reinforcing properties do not reside in the reinforcer itself; factors related to states of the organism (see below) and to response-reinforcer relationships also determine reinforcing effects. The relationship of response and reinforcer usually is described as being purely a temporal one, for the effects of the reinforcer on behavior do not seem to be dependent upon any foresight or purpose on the part of the subject. In this regard, such neutral words as "conditional" or "contingent" to describe the relation of the reinforcer to the response are especially well chosen. Still, to assume that the nature of the response *in no way* influences the reinforcing effects is to disregard some recent experiments which have rather broad implications for our understanding of reinforcement.

One group of experiments has compared the effects of control of some of the characteristics of the reinforcer by the animal with the effects of control by the experimenter. For example, Keesey (1964b) allowed rats to determine the duration of the positively reinforcing electrical brain stimulation which they received. He then tested response rates when a wide range of durations under his control were presented to the rats. In the subject-controlled portions of the experiments, the animals decreased stimulation durations as the experimenter increased either the current or the pulse frequency of the stimulation; when the experimenter controlled the durations, response rates continued to rise as durations were lengthened, even at high currents. Response rates were determined under variable interval reinforcement to minimize

any effects the stimulation itself might have on response rates. It is as if the reinforcing effects associated with dimensions of the stimulation, such as duration, were in part determined by whether the responses of the animals controlled the duration. That the effects were no mere result of a reflexive withdrawal of the rat from the bar after he was stimulated for a certain length of time was shown by a second experiment in which the animals pressed one bar to initiate the stimulation and pressed a second bar, on the other side of the chamber, to terminate the stimulation. Again, the same results were obtained.

A still more striking influence of the response in determining reinforcing properties is seen in an experiment by Kavanau (1963). As one phase of a study of the activity cycles of deer mice (*Peromyscus crinitus*), Kavanau allowed running in an activity wheel to occur under some circumstances only if a bar was pressed (releasing the brake on the wheel), while at other times the wheel was motor driven and pressing one bar could stop the wheel and pressing another bar would start it again. Whether the energy to turn the wheel was provided by motor or mouse, running in the wheel clearly reinforced bar pressing. However, when the experimenter turned on the motor, the mice turned it off; or, if they were running and the experimenter turned off the motor, the mice turned it on again. Hence, to describe the reinforcer as "running" or "presentation of the conditions for running" is obviously incomplete and misleading: it is *running contingent upon bar pressing* which increases the probability of reoccurrence of bar pressing.

Finally, we may mention the technique developed by Steiner, Beer, and Shaffer (1968) to separate reinforcing stimulation from its response contingency. They allowed rats to stimulate themselves, using a variety of reinforcement schedules to manipulate the density of the electrical brain stimulation. A tape recording of the exact pattern of stimulation received by each rat was then played back through the stimulator, but now the bar was arranged so pressing it would interrupt the stimulation circuit. They found that the animals consistently terminated many of the patterns of stimulation which they had produced themselves when the response-contingent conditions were in effect. In other words, exactly the same stimulation may be positively reinforcing when response contingent, or aversive when not response contingent.

These observations point to one of the gaps in our understanding of the phenomenon of reinforcement: Why is it that such "free" (that is, not response-contingent) stimulations are sometimes not reinforcing, or possibly even aversive, when at other times they reinforce whatever response happens to occur, and generate "superstitious" behavior (Skinner, 1948)? Such adventitious reinforcement may systematically increase the probability of rather restricted (and easily observable) response classes, such as turning clockwise or bobbing and bowing the head, or it may increase the probability of a broad class of responses, which may be detectable only as an increase in general activity. Still, we would always expect to find some reinforcing effects if we present such stimuli without regard for the responses of the organism, and we would be surprised if no systematic effects were observed. However, the implications of the studies just reviewed are that such superstitious behavior may not be an inevitable consequence of noncontingent stimulation, that there may be some as yet unknown additional conditions necessary for its appearance, and that, if given the opportunity, animals in some "superstition" experiments might even make an instrumental response to terminate the free stimulations.[33]

Present and past states of the organism
The term "states of the organism" refers to known (or suspected) physiological condi-

[33]For a summary of some of the effects superstitious behavior may have on behavioral experiments, and a consideration of the applicability of the concept of superstitious conditioning to human behavior, see Herrnstein (1966). For further evidence on the importance of the response-reinforcer contingency, see Neuringer, 1970.

tions, some of which modify behavioral processes and thus come to be called "drives" (see Chapter 18). The range of conditions varies from some rather well known and predictable states (such as estrus, hunger, sleep) to some which are more difficult to define and the behavioral consequences of which are less consistent (such as emotion). Many stimuli have reinforcing properties only when appropriate states of the organism exist. For example, we are all aware that a condition of food or water deficit is necessary when first we attempt to use these substances as reinforcers. Usually it also is necessary to reinstate at least some degree of the deficit when again using these as reinforcers. What we actually observe, of course, is the correlation between depriving the animal and his increased probability of eating, but we know that physiological changes are indeed paralleling (and presumably mediating) the behavioral ones (see Chapter 18).

From such observations we sometimes make the unwarranted assumptions that the existence of a reinforcer indicates the presence of an associated physiological state, or that every known physiological state must have reinforcers associated with it. Reinforcing brain stimulation, many forms of stimulus-change reinforcement, certain "highly palatable" substances, and such effective reinforcers as informational feedback, approval and affection, and stimulation of "erogenous" zones of the body need not be associated with any special prior or current physiological states. Furthermore, although most states which have significant behavioral effects can also be shown to increase the effectiveness of certain stimuli as reinforcers, the relationship is neither necessary nor universal. For example, although estrus in the rat is a state with massive influences on both general activity and acceptance of the male, neither presentation of opportunities for copulation nor the sexual activity itself seems to have reinforcing effects for the female (see, for example, Bolles, Rapp, & White, 1968).

An interesting form of the relation between a reinforcer and the states of the organism is shown in those instances in which some specific prior experiences interact with some specific states of the organism, but where neither factor by itself is sufficient to create the conditions necessary for reinforcement. An everyday example with which many readers will be familiar is the reinforcing effect of attention by an attractive member of the opposite sex: It seems reasonable to assume that without either sexual maturity or appropriate experiences, the full reinforcing effects would not be seen. In the laboratory, the contributions of experience and states may be analyzed separately, as in the studies of the reinforcing effects of bird song by Stevenson (1967, 1969). She has shown that male chaffinches (*Fringilla coelebs*) will increase the relative frequency of emission of an arbitrary response (sitting on one of many perches in a large cage) if each such response is followed by a brief recorded segment of song characteristic of that species, but that the reinforcing effects of the song depend on both the prior experience of hearing the song and on the sexual maturity of the bird. If a juvenile male is trapped in the autumn of his first year, after having heard mature males singing in courtship and in marking their territories (Marler, 1956), and if he is then brought to sexual maturity in the laboratory with injections of testosterone, the recorded song will be an effective reinforcer. If he is not given testosterone, the song is not reinforcing. That the reinforcing effects do not derive from testosterone itself is shown by the lack of a reinforcing effect when hand-reared birds (who never have heard any bird song) are injected and tested. It thus seems that the effects of the prior experiences are latent until sexual maturity; only then does the song have reinforcing effects, and neither familiarity with the song nor sexual maturity by itself is sufficient to produce the reinforcing effects. Whether the autumn-caught male birds bring to the laboratory any relevant experiences other than just having heard the songs (for example, encounters with more mature males) is not yet known.

Other Properties of Reinforcers

In addition to the defining property that is, of course, shared by all reinforcers, there are other properties that are quite commonly found in some but not all instances. For example, stimuli which are reinforcers frequently can be shown to have acquired discriminative properties, in that the presentation (or the withholding) of the reinforcer may serve as the cue that further reinforcements are (or are not) immanent. In the *mixed schedule of reinforcement,* two or more schedules are intermixed without any correlated stimuli to mark off which schedule is in effect at any moment, and to the extent that differential behavior develops, we may assume that the discriminative stimuli must have come from the reinforcers themselves. Suppose the program calls for periods of continuous reinforcement (every response reinforced) to alternate with periods of extinction (no reinforcement): This would constitute about the most simple possible mixed schedule, and most organisms soon would begin to show fairly rapid responding as long as each response is reinforced, but slower rates as soon as one of the responses was not reinforced.

Of course, the mere fact that organisms do come under the control of the discriminative properties of reinforcers presents additional problems for the experimenter to whom this source of differential responding may represent a contamination of his main effects (for example, stimulus detection). Several possible means of avoiding or minimizing such difficulties have been suggested by Blough (1966). One obvious solution, of course, is to run a mixed-schedule control group along with each discrimination experiment. Thus, if one were studying the discrimination of auditory stimuli, and one tone was always present during occasional (variable interval) reinforcement while another tone was always present during extinction, a comparable set of subjects could be run with exactly the same conditions except that the tones would be omitted. The differential responding of this mixed-schedule control group then would indicate how much "discrimination" could be expected if the tones were completely absent (see Sadowsky, 1969), and the extent to which differential responding with tones exceeded that without tones would provide an estimate of the control of behavior exerted by the tones. Furthermore, if one were not interested in transient phenomena (such as acquisition of control), the same subjects could be run sometimes with and sometimes without the tones, thus allowing a direct comparison of within-subjects differences.

Reinforcers also will frequently have demonstrable motivating properties. In this case, by "motivating properties" we refer to the increased vigor or speed of responding when these dimensions of behavior are not themselves reinforced. For example, when stable variable-interval behavior has been established, neither increased force nor increased rate of responding will influence reinforcement because the organism already has settled down to making responses at an intensity and a rate that exceed minimum requirements. If we now increase the amount of food in each reinforcement, we are highly likely to observe both an increase in the rate and the force with which the subject responds, but because neither is specifically differentially reinforced, a gradual return to previous levels is to be expected (see Keesey & Kling, 1961). In this case, motivational and reinforcing properties are congruent, but in some instances, they may change in rather different ways. For example, if some minimal interresponse time is required, so that there is differential reinforcement of low rates (the DRL schedule of reinforcement), rapid responding continually resets the timer which must "time out" (complete its timing cycle) before the next response may be reinforced. After 30 or 40 hours of exposure to a schedule that requires, for example, a minimum interresponse time of 30 seconds, most rats will show a peak in their distributions of the interresponse times in the general region of 30

seconds. If the amount of food per reinforcement is then increased, the animal responds more rapidly, thus reducing the number of reinforcements (Beer & Trumble, 1965). The food is still selectively reinforcing responses which follow pauses of at least 30 seconds, but the increase in amount of food per reinforcement has also wrought a change that seems consistent with the expression "increase in motivation."

If stable behavior is established and then reinforcement is terminated, the subject may respond with greater speed and vigor rather than less. In this case, the change usually is labeled "frustration," and it is thought to reflect yet another variety of motivational effect. Under conditions of complete omission of further reinforcement, this increase is transient and may appear as a "hump" on the extinction curve (Sheffield, 1949; Stanley, 1952; Thompson & Bloom, 1966). However, relatively stable frustration effects can be obtained in certain situations. For example, Amsel (1958) has developed a technique in which the animal is reinforced in a goal box located halfway down an alley, and then immediately thereafter is reinforced in the second goal box for running the rest of the way down the alley. Omission of food in the first goal box characteristically creates an increase in speed in the second segment, an effect which has been labeled the "frustration effect" by Amsel.

This use of the terms "motivation" and "frustration" to describe observed changes in behavior is a convenient form of expression, but we should avoid the all too natural tendency to use such labels to explain the phenomena. We also should draw a clear distinction between "motivation" as used in this context and such more formal, theoretical terms as *incentive motivation* (see Chapter 18). Incentive motivation is one of the central factors in the Hull-Spence-Logan behavior theory (see, for example, Logan, 1960), and it is given the properties of energizing behavior (along with other motivational factors) and of being proportional to the amount and quality of the reinforcer. The mechanism by which incentive motivation is thought to operate is the "anticipatory" response appropriate to the reinforcer. For example, if the reinforcer be food, such portions of the seizing, chewing, and swallowing complex as can occur in the absence of the food are thought to be conditioned to stimuli present while the animal is eating, and on later occasions these anticipatory responses are assumed to be emitted when the animal is in the presence of similar stimuli. Because there is direct evidence that such anticipatory responses do indeed exist and do serve behavioral functions (see p. 622), the theory seems to offer an interesting and internally consistent view of at least a part of the mechanism whereby ingested reinforcers may influence later behavior. Where other reinforcers are involved (and indeed the bulk of everyday reinforcers would fall in this category), overt consummatory responses are rare. For example, attention and recognition from others and informational feedback from the environment have demonstrable reinforcing properties, but what is the anticipatory response which we make in such situations? The theory could postulate that central nervous system correlates of such responses might serve functions similar to that of anticipatory chewing, but such extensions take us quite beyond currently available techniques for observation and evaluation of neuronal processes.

Motivation and reinforcers also are closely intertwined in the "drive induction" theory developed by Sheffield (for example, 1966; see also p. 657). Sheffield has suggested that Pavlovian conditioning presents a better picture of "the learning process per se" than does behavior in the operant situation (1965, p. 320). The latter, suggests Sheffield, is probably more related to problems of motivation than to learning, for (in his analysis) the crucial fact about what we have been calling "reinforcers" is that they elicit unconditioned responses which consummate (that is, terminate) striving toward them. This motivated striving arises because stimuli associated with

the reinforcers become (classically) conditioned stimuli for the appropriate consummatory responses, but until the reinforcer itself is reached, the consummatory responses cannot occur. For example, if food is always given in a white goal box, stimuli from the goal box will become the conditioned stimuli for eating responses, but until the food is actually reached, no eating can occur. The occurrence of such unconsummated responses is said to be "innately exciting," and the excitement is thought to be channelled primarily into skeletal behavior, thus producing a more active organism. If these assumptions are granted, it follows that the organism will be more active when in a white alleyway than when in a dissimilar situation (for example, when in a black alleyway). In this fashion, the organism is led (as it were) toward the reinforcer by his excited activity. When the organism finally makes contact with the reinforcer, the occurrence of consummatory responses brings striving to an end, and at the same time provides one more pairing (in the Pavlovian sense) of stimuli associated with the reinforcer and the reinforcer itself.

Furthermore, the attempt to organize all problems of reinforcement around the idea that each reinforcer has an associated consummatory response, some portions of which occur as conditioned (and excitement-producing) responses, seems apropos for food, water, or sex objects, but (as in the case of incentive motivation, discussed above) the analysis seems strained when we attempt to apply it to the broad spectrum of reinforcers, many of which have no identifiable consummatory responses. Another key assumption is that every reinforcer "inherently carries a component of relaxation" (Sheffield, 1965, p. 318) that brings striving to an end, but (as we have seen) there are some very effective reinforcers (such as electrical brain stimulation) which seem to create more excitement and generate more activity after they are presented than before.[34]

In summary, although problems of motivation certainly overlap those of reinforcement, they are not identical, nor does it seem that any single motivational characteristic is common to all reinforcers.

Increasing the Probability of Response

In defining reinforcement, we specified that the probability of the response must be increased, but we can see that it is not just the probability of the response in general, but of the response in the *presence of certain stimuli* that is increased. These stimuli (or "cues") may come from persons (parents, teachers, traffic policemen . . .) who seek to guide our behavior; from static features of the environment, allowing us to behave differently in the bedroom and the ballroom; from reinforcements themselves, allowing us to discriminate between periods of reinforcement and nonreinforcement. Some of these cues may arise from the properties of the stimuli themselves (such as the color of the traffic light) while others may depend upon temporal organizations within a series of stimuli (as in Morse code) or may be produced by the behavior of the organism itself (for example, kinesthetic stimuli).

In some experimental situations and in most examples from everyday life, our stimuli are so poorly controlled and so difficult to identify that we are forced to give up attempts to manipulate them directly. The rat being shaped to press a bar is a familiar example of this difficulty: We cannot specify the stimuli which come to control the behavior of bar pressing, but we infer their presence from the fact that the well-trained rat emits a smooth pattern of behavior, pressing the bar and seizing food pellets from the food cup each time the feeder mechanism is activated. Because he does not press the food cup nor

[34]Such apparent exceptions to the suggestion that reinforcers terminate striving could be multiplied many times. For example, fighting cocks will peck a key repeatedly if key pecks allow them to see another cock, or a reflection of themselves (Thompson, 1964). Each glimpse creates great excitement in the cock and increases his "striving," yet the operation of presenting the view of another animal clearly is reinforcing, for key pecking is increased and then maintained at high levels.

run to some far corner of the chamber when the feeder mechanism clicks, we conclude that the probability of bar pressing in the presence of stimuli associated with the bar has been increased, and the probability of approaching the food cup has similarly been increased when the rat is in the presence of such stimuli as the click of the feeder.

However, the control exerted by such stimuli is not inflexible in the sense that spinal reflexes are inflexible, and minor modifications in the stimuli do not produce gross disruptions of the behavior. To some of the keenest observers of animal behavior, the fact that the animal can adjust to minor changes in the situation implies that the behavior is purposive and goal directed (see, for example, Tolman, 1932; Thorpe, 1963) or that such behavior might well be called "voluntary" to distinguish it from instinctive or reflexive behavior in which the controlling stimuli, the responses, and the consequences are related in an invariable manner (Teitelbaum, 1966). On the whole, little use has been made of such classifications, and many would agree with Skinner (for example, 1953, 1966) that the labels may even misdirect attention from important research problems.

The control of responses by stimuli correlated with reinforcement is readily demonstrated by systematic manipulation of such stimuli. In some of the earliest studies of this type, the procedures were modeled on the Pavlovian arrangement, using, for example, the method of discrete trials. For example, Grindley (1932) restrained guinea pigs in a holder, sounded a buzzer, and when a head movement of a predetermined direction and angle occurred, he stopped the buzzer and delivered a bit of food to a food cup directly in front of the animal. Although there was an overall increase in the frequency of such head movements, the relatively greater increase in the presence of the buzzer demonstrated the reinforcing effects of food. Presumably, the selective increase in responding in the presence of the buzzer occurred because the complex stimulus of (buzzer plus other stimuli plus head movement feedback) was followed by food while the complex stimulus of (other stimuli plus head movement feedback) was not.

Such discrete-trial procedures introduce a vexing problem for the experimenter: The responses sometimes occur between trials, and the experimenter is left to guess whether, if he starts a trial just now, the behavior might not begin to appear just before he is ready and thus spoil his procedure.[35] Furthermore, the control of the spacing of the trials by the experimenter frequently introduces discontinuities into what seems to be continuous behavior, which may cause additional variability in the data.

For such reasons, many experimenters have adopted procedures which do not involve trials at all, or which allow the subject to determine when each trial is to be initiated (see p. 602). From such situations, the patterning of behavior correlated with reinforcement schedules frequently emerges as one of the most interesting results. For example, if every *n*th response is reinforced (the *fixed ratio* schedule), a characteristic response pattern emerges, showing a post-reinforcement pause followed by responding at a relatively constant rate. What are the stimuli which govern the emission of such behaviors? Since the pause prior to the start of the response run is relatively insensitive to the size of the ratio requirement, and since an interruption of the procedure immediately after reinforcement (for example, by introducing a blackout which suppresses pigeon responses) will eliminate the pause (Ferster & Skinner, 1957, p. 117), it is concluded that the pause in ratio schedules develops because one reinforced response can never follow immediately after another. Hence, responding in the presence of the stimuli resulting from reinforcement never is reinforced, and thus such responding is extinguished. From this it follows that anything which disrupts such reinforcement after-effects (such as a blackout) will also disrupt these stimuli and thus the start of responding should be hastened. On the other

[35]See Sheffield's comments (1965, p. 314) on this problem in the Pavlovian situation.

hand, reinforcement in ratio schedules would almost never occur after long pauses in responding, but almost always would occur when response follows response in close order. Thus, the stimuli in the presence of which responding is reinforced should be expected to include the after-effects of having just responded, and once a response or two has been emitted, the feedback from such responses should provide the necessary discriminative stimuli for the emission of a run of responses at a rate characteristically emitted under those conditions (see Ferster and Skinner, 1957, for a behavioral analysis of such schedules). Note that even though we have not directly observed either the stimuli produced by responding or the post-reinforcement stimuli, the assumptions that they exist and that they are discriminative stimuli for characteristic response patterns is consistent with what we know about behavior in situations where we can manipulate the stimuli directly; it is also consistent with the indirect evidence just cited (such as inserting blackouts). Again, we conclude that presentation of reinforcers does not increase the probability of the response in an indiscriminate fashion, but instead, that the response shows a selective probability increase in the presence of those stimuli correlated with reinforcement.

Although it seems valuable to assume that the stimulus consequences of each response in ratio runs may in part set the occasion for the next response, we should not assume that each response is necessarily emitted only when stimuli from the immediately preceding response are present. Although such response chains do, of course, play important roles in behavior, there are some response sequences which, as Lashley (1951, p. 123) pointed out, occur with such rapidity that neural impulses from kinesthetic receptors could not possibly reach the central nervous system in time to initiate the activity in motor areas needed to initiate the next response. Instead, it seems that learned responses may become integrated into sequences which then can be run off as units, without requiring response-produced stimuli as the alternate links in a behavioral chain. The movements involved in speaking, typing, or playing musical instruments are everyday examples of sequences of this type.

The problem of analyzing the effects of a reinforcer on behavior is complicated even more if we select a behavioral situation in which the response in which we are interested is not identical with the response we reinforce. Consider a simple position discrimination in a T maze: We select one of the two alternatives as "the response" to be reinforced, but then we actually reinforce the last bit of locomotion into one of the goal boxes. At the choice point in the maze, the animal may show behavior that varies considerably from trial to trial, but if he eventually arrives in the proper goal box, these last few responses are reinforced. Of course, entering that alley from the choice point always precedes (by various intervals) the reinforced response, while other responses which might occur (for example, sniffing, turning around) are less likely to be perfectly correlated with reinforcement, and so eventually the turns toward the "correct" goal box become more and more probable. Although crude, the maze procedure "works," in that species from earthworm (see, for example, Yerkes, 1912; Robinson, 1953) to man (see, for example, Stellwagen & Card, 1965) can be "tested" in this manner, but it is exceedingly difficult to specify and measure with precision the responses which are reinforced or the stimuli in the presence of which that response class is emitted.

A somewhat similar problem exists for reinforcement schedules in which the crucial features of the reinforcement contingencies are not specified in behavioral terms. Interval schedules, or schedules that require some minimal interresponse time, disregard all the emitted behavior except the response that follows the completion of the time interval. In effect, we are leaving to chance the determination of the behavior during the interval, and because we usually are not interested in (nor prepared to measure) idiosyncratic behavior, such procedures may be less useful

tools for us to use to analyze reinforcing effects than schedules which allow the experimenter to specify more completely the behavior which will be reinforced.

What we see, then, is that presentation of a reinforcer contingent upon the occurrence of a response increases the probability that the response will occur again and that the stimuli in the presence of which this process is carried out will exert some control over the emission of the response. However, we should not assume that just any and all stimuli impinging on the organism conjointly determine when the subject will make such responses again. Instead, it seems that stimuli present when the response is reinforced, and absent when the response is either not reinforced or cannot be made, are the only stimuli which gain any significant degree of control over that response. For example, in the process of training rats to press a bar, responses of raising the paws and pressing on the food-cup are *not* reinforced, while the same behavior in the presence of stimuli from the bar is followed by delivery of the food pellet. In this sense, stimuli from the bar are discriminative stimuli, but because we cannot systematically vary such stimuli along any dimensions, we have little chance to evaluate the degree of control they exert over responding. When the subject faces away from the bar, the stimuli characteristic of that part of the environment always are paired with the subject's not making the bar pressing response, and so they too probably come to control important aspects of behavior (such as turning toward the bar), much as presenting a key color to a pigeon and withdrawing it rapidly before he can peck the key eventually establishes that color as a discriminative stimulus in the presence of which the pigeon does not peck (Terrace, 1963; see p. 778).

Here, then, we have a further modification of our description of how reinforcers function, for it is not just any and all stimuli present when a response is emitted that later will determine when and where the response will occur, but only those stimuli that are present when the response is made and is reinforced, and absent when the response either is not reinforced, or when the subject cannot make the response. Thus, the "Law of Operant Reinforcement" might be stated in this fashion:

Reinforcement increases the probability that the operant will be emitted in the presence of stimuli differentially associated with reinforcement.

> At this time, it certainly is premature to attempt to make any restriction on the term *operant* other than to identify it with responses whose probability can be increased through presentation of reinforcers. All variety of skeletal responses have been shown to be sensitive to such reinforcing operations, and smooth and cardiac muscle responses and even tissue secretions may also be modified through the same procedures (Miller & Banuazizi, 1968). This use of "operant" does not really represent an extension of the original meaning of the term (Skinner, 1937), for in these recent experiments the intestinal movements or changes in heart rate have been given the same basic property as other operants; namely, they control the occurrence of reinforcers and hence operate directly upon the organism's environment.

Role of Reinforcement in Acquisition of Stimulus Control

We have been referring to the fact that after reinforcement, the emission of one class of responses may occur primarily in the presence of one set of stimuli, and that, with changes in stimuli, there may be correlated changes in responses. In recent years, the phrase "stimulus control" has come to be used in contexts where formerly it might have been said that the subject "discriminated the stimuli." Certainly "stimulus control" is a more neutral term, being free of connotations that the subject is always aware of the stimuli that are influencing his behavior. It also avoids the possible confounding of *processes* with observed *functional relations* (Terrace, 1966a). Most users of the term follow Terrace in identifying the degree of control with the change in response probability as a stimulus dimension or continuum is explored. Thus,

"stimulus control" refers to control by stimuli that the experimenter can vary in some systematic manner. Of course, this leaves many sources of stimulation which certainly must exert some control over responding, but which we can manipulate only in the most gross sense. One obvious example is the stimulation produced by the animal's behavior: Considering just the intensive aspects, we can make responses somewhat more or less effortful by manipulating the force required to operate the bar (see, for example, Notterman & Mintz, 1962, 1965) or by placing weighted packs on the animal's back (Solomon, 1949), but we have no direct evidence that this produces systematic changes along a single dimension of stimulation. Still, the orderly effects of such manipulations on behavior imply that the procedures produce stimuli which control some aspects of behavior, and it is such (stimulus) control which is left outside current definitions of *stimulus control.*

We then may ask the question: Is reinforcement essential for the acquisition of the control of responses by stimuli? If we restrict our attention to typical operant conditioning paradigms, the answer almost certainly would be "yes" (Terrace, 1966a). However, if we include in our survey such procedures as imprinting (see, for example, Bateson, 1966) or perceptual or exposure learning (see, for example, Gibson, Walk, & Tighe, 1959) we see that significant influences on subsequent responding can be produced merely by presenting stimuli under appropriate conditions, in situations where no demonstrable reinforced responses occur and where no known differential association of the stimuli with reinforcement takes place.[36] In such studies, systematic explorations of possible dimensions of the stimuli usually are not included, but at least one experiment (Cofoid & Honig, 1961) examined wave-length generalization of responses to an imprinted stimulus and obtained gradients suggestive of stimulus control. Outside operant paradigms, therefore, it would seem that at least some degree of stimulus control can be established without obvious differential reinforcement.

Does the nature of the reinforcer influence the acquisition of stimulus control? If each organism is trained on two or more discrimination problems, each with a different condition of reinforcement (such as different amounts of food per reinforcement), differences in the rate with which the discrimination problems are solved have been consistently reported (for example, Schrier & Harlow, 1956; see p. 639). If each organism is trained with but one condition of reinforcement, the results are less clear, but the evidence suggests that there are at least some conditions under which the amount of reinforcement and the speed with which the discriminations are solved are positively correlated (see, for example, Schrier, 1956; Waller, 1968; Keesey & Lindholm, 1969). Common sense suggests that, other things being equal, the larger or the more preferred the reinforcer, the faster the organism should master the problem we give it. However, as we have seen (p. 617) when we are varying food reinforcers, other things are rarely equal. In Waller's experiment, for example, providing different amounts of food to different groups resulted in different durations of exposure to the stimuli correlated with reinforcement; and adequate adjustment of preliminary training required that every animal be exposed to all the amounts of food used in the experiment. These and similar problems seem inherent in studies in which the amount of food reinforcement is manipulated and seem to require that we use some degree of caution when we conclude that differences in reinforcers produce differences in rate of acquisition of stimulus control when each organism is exposed to but one condition of reinforcement.

Many of these practical problems can be avoided if we use electrical brain stimulation. For example, in studying amount of reinforcement, such dimensions as the intensity or the

[36]See pages 579–581 for a description of such procedures.

duration of the stimulation can be manipulated independently. Furthermore, each of these dimensions is continuously variable, allowing us to adjust the reinforcer so that some specific behavioral result (such as a certain response rate) can be obtained from each animal. Using this reinforcer, and food controls for comparison purposes, Sadowsky (1969) found the rate of acquisition of a discrimination between two auditory stimuli to be almost exactly the same for high- and for low-reinforcement groups. After obtaining stable rate-intensity functions (see p. 546) for each animal, he picked out some that responded rapidly at low current and others that responded rapidly at high current. He also found some animals that responded at low rates to high currents, and others that responded at low rates to low currents. He thus created four groups, two of which were made up of rapid responders, and two of slow responders. (Some animals, of course, fell in between the "high" and "low" points, and were therefore consigned to a subsequent experiment.) Then, all the rats were trained in a chamber containing a single bar, where responses in the presence of one auditory stimulus were reinforced (on the average) every 30 seconds, while all responses in the presence of a second auditory stimulus went unreinforced. The rate with which these auditory stimuli came to control the responding was almost exactly the same for all four groups, indicating that rather large differences in the physical characteristics or in the behavioral consequences of reinforcers may have little (or no) effect on the acquisition of stimulus control of behavior.

Of course, this is but one type of discrimination situation, and the results may be peculiar to it, but other recent studies seem to support the generality of these findings. For example, if we ask how fine a discrimination can be obtained using different reinforcers, we find that food and electrical brain stimulation seem to be equally effective when tested in a two-choice brightness discrimination, where the difference between the discriminative stimuli was gradually reduced until differential responding disappeared (Terman & Kling, 1968).

Thus, both rate of acquisition and final level of stimulus control seem remarkably insensitive to rather marked differences in reinforcers. What might be thought of as the obverse effect has also been investigated: Once differential responding has been established, do differences in reinforcers promote differences in generalization? In this experiment (Kling & Berkley, 1968), three groups of rats were trained in a successive discrimination problem using two auditory stimuli and either food pellets or electrical stimulation of the hypothalamic or septal regions of the brain as reinforcers. After attaining a moderately strict criterion of discriminative responding, each animal was tested with the two training stimuli plus four other frequencies. Both the shapes and the relative breadth of the generalization gradients were found to be comparable for all groups (see p. 656 and Figure 15.18).

Although these studies sample but a minute portion of the possible conditions under which stimulus control may be studied, there is already a strong suggestion that differences in reinforcers—even when they produce marked differences in response rates, consummatory behavior, resistance to extinction, and so on—may be relatively unimportant as far as the control of responding by correlated stimuli is concerned. Again, we must urge caution in extending these observations to other situations, for, as we have noted, there seem to be some conditions under which reinforcer differences do influence stimulus control (for example, Keesey & Lindholm, 1969). Unfortunately, we as yet have no insight into the characteristics of situations in which such reinforcer effects will be found.

We are left, therefore, with the tentative conclusions that reinforcers are essential to increasing and maintaining the probabilities of operant behavior; that differential association of stimuli with reinforced responses and with non-reinforcement is essential to the

establishment of stimulus control of behavior when operant training methods are employed; that differences in reinforcers have relatively more influence on response rates if each organism is given more than one reinforcement condition than if a single reinforcer is used for each subject; and that while differences in stimulus control certainly are enhanced by exposing each organism to more than one condition of reinforcement, differences in stimulus control obtained when each subject is trained with just one reinforcer are likely to be small and—in at least some cases—may not be seen at all.

Of course, in practical situations (as in the schoolroom), there would rarely be circumstances in which only one condition of reinforcement were used, and thus the last conclusion (above) refers to a problem that has little everyday significance. It is, however, of considerable theoretical importance, for a clear answer to the question of whether all reinforcers make equal contributions to the acquisition of stimulus control would add considerably to our understanding of the phenomenon of reinforcement.

We have organized our survey of positive reinforcement around some of the topics that have been most actively investigated during the last decade. In the process, we have offered a few conclusions where the evidence seems to warrant them, and pointed to gaps in our knowledge or inconsistencies in the published data with the hope that students will see some of these problems as challenges to their ingenuity and skill. Looking into the future, we might hazard the opinion that the next decade will see the fracturing of "reinforcement" into several less global phenomena, each of which would be concerned with a relatively limited set of problems. Paralleling this trend, we would not be at all surprised to see a marked increase in the number of species employed in studies of reinforcement, as the potential contributions of behavioral genetics (for example, McClearn, 1963) and ethology (Hinde, 1966) to the study of reinforcement become more widely recognized. The assault on the neuronal basis of behavior modification can be expected to become even more active than it has been in the last few years, and here we may look for the techniques developed in the study of reinforcement to be especially valuable contributions, for without appropriate behavioral methodology, biochemical or electrophysiological investigations of learning processes will lack the criteria against which they can be evaluated. Finally, it is fairly safe to predict that applications of the laboratory procedures to educational problems, especially those of the nursery and primary schools, will become far more widespread than at present, thus justifying in part the support by society of basic research into problems of reinforcement.

Russell M. Church

AVERSIVE BEHAVIOR

16

Noxious stimuli produce a variety of behavioral effects that will be examined in this chapter. The onset of such stimuli arouses emotional reactions of distress, and their termination induces relief. The onset and termination of a previously neutral stimulus that has preceded a noxious stimulus also arouse emotional reactions. An animal will attempt to escape from a noxious stimulus, and to delay or prevent its occurrence. If a noxious stimulus occurs immediately after a response, or if a response maintains such a stimulus, an animal will reduce its tendency to perform the response.

Unfortunately, none of these behavioral effects is a generally accepted and universally applicable definition of a noxious stimulus. A stimulus that would be classified as "noxious" by one set of criteria might not be so classified by another set of criteria. Perhaps the most satisfactory definition would rely upon a preference measure, that is, a stimulus is noxious if and only if a subject reliably chooses a "neutral" alternative over it. Of course, the noxiousness of a stimulus depends, in part, upon the motivational state of the subject. A cool breeze may serve as a noxious stimulus to a subject in a cold environment but as a positive reinforcing stimulus to a subject in a hot environment. Usually, however, studies of aversive behavior employ a stimulus so noxious that it would not be questioned (for example, intense electric shock), and thus no formal definition is required.
Figure 16.1. General circuit diagram of apparatus to administer electric shock. *R* = relay switch contacts, *C* = fuse, *A* = variable autotransformer, *T* = transformer, *M* = voltmeter, *V* = variable resistance, *F* = fixed resistance, and *O* = output.

Many different noxious stimuli have been used in studies of aversive behavior. A loud noise (Watson & Rayner, 1920), a slap from a lever (Skinner, 1938), a bump on the nose and a fall into a net (Maier, 1949), presentation of a toy snake to a monkey (Masserman & Pechtel, 1953), and a swat with a rolled-up piece of newspaper (Stanley & Elliot, 1962) have been used to punish a response. Omission of a usual positive reinforcer may also serve as a punishment (Wagner, 1969). Loud noises, bright lights, pinches, heat, cold water, blasts of air, and a variety of other unpleasant stimuli have been used to produce escape and avoidance behavior. Nonetheless, electric shock has been employed in a large majority of the studies of aversive behavior, for the characteristics of this stimulus are particularly easy to measure and control.

Further research on aversive behavior should make use of noxious stimuli other than electric shock, particularly stimuli that arouse emotional responses other than pain and fear (for example, discomfort, annoyance, anger, nausea). Such work would extend the generality of conclusions about aversive behavior that are now based on the use, primarily, of only one noxious stimulus, electric shock.

METHODS FOR ADMINISTERING ELECTRIC SHOCK

Since the early 1900s electric shock has been used by psychologists to motivate behavior, and many different devices have been used to generate this noxious stimulus. The first experiments used direct current from dry cells (for example, the work of Yerkes, 1903), but these were soon replaced by induction coils (for example, by Yerkes and Dodson, 1908). After alternating current became generally available in psychological laboratories it was widely used as a noxious stimulus. Most research of aversive behavior now makes use of a simple circuit only slightly modified from that used by Jenkins, Warner, and Warden (1926) in their investigation of the obstruction technique.

The Shock Circuit

A general circuit diagram of apparatus used to administer electric shock is shown in Figure 16.1. The autotransformer (*A*) controls the voltage input to the power transformer (*T*), up to about 135 V. This transformer increases the voltage to a value that is measured by the voltmeter (*M*). A fixed resistance (*F*) and a variable resistance (*V*) can both be used to control the voltage output (*O*) applied to the subject. To administer shock the experimenter closes the switch, which normally would be the contacts of a relay (*R*). For the protection of the subject, experimenter, and equipment, the apparatus to administer electric shock should always contain a fuse (*C*), a fixed resistor (to limit the maximum current), and a transformer (to isolate the output from the ground).

In such a circuit the experimenter has control over two variables, the source voltage and the resistance in series with the subject, but the subject has control over the third variable, its own impedance. Ideally, one would select a shock circuit in which the experimenter had maximal control over the effective characteristics

of the stimulus. Because the subject's impedance is not under the experimenter's control, the experimenter should select a circuit in which variation in the subject's impedance makes little difference in the effect the shock has on responding, that is, the behavior at any particular setting of the source voltage and fixed resistance should be relatively constant. But what is the effective characteristic of the electric shock? Is it the voltage across the subject (volts, E), the current passing through the subject (milliamperes, mA), or the power dissipated in the subject (milliwatts, mW)?

The impedance of a rat receiving a moderately intense foot shock is approximately 150,000 Ω (ohms), and it decreases with increases in the intensity of the shock (Campbell & Teghtsoonian, 1958). If, with respect to the impedance of the subject, the series resistance is small (for example, 10,000 Ω for a rat receiving moderately intense foot shock), then a *constant-voltage* shock circuit is approximated. With this shock circuit a large change in the impedance of the subject makes only a small change in the voltage applied to the subject. This statement follows from Ohm's Law, $I = E \cdot R$, in which E is the voltage at the output of the transformer, I is the current, and R is the total resistance of the circuit.

If, with respect to the impedance of the subject, the series resistance is large (for example, 2,000,000 Ω for a rat receiving moderately intense foot shock), then a *constant-current* circuit is approximated. A large change in the impedance of the subject makes only a small change in the current passing through the subject if this circuit is used. A constant-current circuit usually consists of a transformer with an output of about 500 V, no autotransformer, a fixed resistor of 150,000 Ω, and a variable resistor (potentiometer or decade resistor of 0 to 5,000,000 Ω) for adjustment of intensity.

A series resistance matched to the impedance of the subject (for example, 150,000 Ω for a rat receiving a moderately intense foot shock) is better than any other fixed resistor for holding constant the power ($P = I^2 \cdot R$). A *matched-impedance* shock circuit usually consists of an autotransformer for adjusting intensity, an isolation transformer with an output voltage equal to the input voltage, a fixed resistor of 150,000 Ω, and no variable resistor. If the fixed resistance is no less than 150,000 Ω and the voltage at the output of the transformer is no greater than 500 V, by Ohm's Law and the definition of power, the transformer need not be rated for more than 4 mA, and 2 W resistors should be satisfactory.

Campbell and Masterson (1969) have provided a thorough treatment of the relative merits of various shock sources. They have come to the conclusion that shock circuits with high source voltages (over 500 V) may cause large variations in current density and even sparks between the subject and the grid. Shock circuits with low resistance (below 150,000 Ω) may result in an increase in effective intensity through time due to a positive feedback mechanism. (A decrease in the impedance of the subject results in an increase in intensity of the shock that leads to a further decrease in the impedance of the subject.) All shock circuits that are adequate to supply a shock of the required intensity and that consist of (1) a series resistance of 150,000 Ω or more, and (2) a source voltage of 500 V or less,
Figure 16.2. Diagram of lever box with grid floor and scrambler. The front wall of the box contains a food cup and a lever; the grid floor is attached to the output of a scrambler and four of these connections are shown in the diagram.

however, are about equally satisfactory. In a preference situation with rats, using shock circuits with 150,000 Ω or 600,000 Ω resistance, and with a constant current circuit of 500 V, Campbell and Masterson (1969) found slightly over 25 jnd's between the aversion and tetanization thresholds.

The Electrodes

If two electrodes are *directly* attached to a subject, the experimenter has control of the current density (because the area of contact is constant). This method is generally employed when the subject is restrained, although it is sometimes used when the subject is permitted to walk around in an experimental enclosure. Electrodes may be attached to the surface (Hoffman, 1960; Azrin, Hopwood, & Powell, 1967; Weiss, 1967), implanted under the skin (Azrin, 1959; Feirstein & Miller, 1963), or located in areas of the brain that presumably produce pain or fear when stimulated (Delgado, Roberts, & Miller, 1954).

There are a number of technical problems related to the administration of electric shock to a freely moving animal by means of attached electrodes, not the least of which is that the animal may dislodge the electrodes unless an excellent swivel arrangement is used to keep the wires out of reach all the time. Therefore, most studies of aversive behavior of freely moving animals use apparatus with a grid floor (for example, a shuttlebox, runway, T-maze, or lever box). The grid usually is constructed of stainless steel bars (about 3/16th in. diameter and 1/2 in. apart) that are inserted into an acrylic insulator that is placed outside the part of the apparatus accessible to the subject (see Figure 16.2). The bars should be cleaned frequently to prevent the accumulation of foreign deposits that can serve to decrease the contact between subject and bars. Also, the insulator supporting the grid should be cleaned to prevent the formation of any conducting film, and feces and other matter should be removed from adjacent grids to prevent current flow through loads other than the subject.

The Scrambler

If shock is administered only for a fraction of a second (as in some punishment studies) it may be feasible to interconnect alternate bars (that is, bars 1, 3, 5, and so on to one side of transformer output, and bars 2, 4, 6, and so on to the other). Some of the bars of the grid are constantly kept at the same polarity as some other bars, however, and the subject may avoid shock by remaining in contact with only those bars. If the shock is administered for more than a fraction of a second, a subject may find such a position. Because it is obviously undesirable to push the subject, shake the apparatus, or discard a subject that adopts such a position, a variety of units have been devised to shift the relative polarity of the bars. With such a unit (a "scrambler") a subject cannot make contact with two different bars that are always at the same polarity. In terms of components, a scrambler can be made from stepping switches, cam-operated microswitches, motor-driven commutators, and relays, among other devices.

Ideally, any particular bar would be at opposite polarity from any other bar exactly half of the time, but such a device would require $n!/[(n/2)!(n/2)!]$ different patterns. Because this arrangement would become unwieldy if 16 or more bars were attached to the device, most scramblers either do not switch all pairs of bars equally often to opposite polarity (for example, see Skinner & Campbell, 1947) or switch only one bar to opposite polarity from all the others at any given instant (for example, Wyckoff & Page, 1954).[1] A close approximation to a practical scrambler in which each bar is at opposite polarity from each other half the time has been described by Brush (1967).

BASIC PROCEDURES

In any study of aversive behavior there are five classes of stimuli that should be distinguished: (1) experimenter-controlled stimuli, often referred to simply as "stimuli," (2) response-produced stimuli controlled by the subject, often referred to simply as "responses" because they consist of the proprioceptive, visual, auditory, and other consequences of responses, (3) outcomes or events, both rewards and noxious stimuli, (4) temporal stimuli that must be defined as

[1]The diagram of the scrambler in Figure 16.2 has the properties that each pair of bars is equally often at opposite polarity and only one bar is at opposite polarity from all the others at any given instant. One side of the output of the shock source is wired to the normally open contacts of a set of switches, and the other side of the output is wired to the normally closed contacts. The common contact of each switch is wired to a bar of the grid floor. An animal may receive shock if it is standing on bars of opposite polarity (for example, the last bar and any others in the diagram). To change the relative polarity of pairs of grids rapidly, a magnet may be rotated at several revolutions per second to operate, in sequence, the magnetic switches that are mounted in a circle.

beginning from one of the previous kinds of stimuli, and (5) situational stimuli, the relatively fixed aspects of the environment or the apparatus. Each of the basic procedures for the study of aversive behavior can be described in terms of the contingency between a noxious stimulus (its onset or termination) and some other stimulus.

Classical Conditioning

In aversive classical conditioning a noxious stimulus is contingent upon an experimenter-controlled stimulus. For example, in classical eyelid conditioning a puff of air to the eyelid (a noxious stimulus) may follow 1/2 second after each presentation of a light (an experimenter-controlled stimulus); in classical conditioning of the heart rate an electric shock (a noxious stimulus) might be given 10 seconds after each presentation of a tone (an experimenter-controlled stimulus). In all cases of aversive classical conditioning, the task for the subject is to learn the relationship between an experimenter-controlled stimulus or conditioned stimulus (CS) and a noxious stimulus, one kind of unconditioned stimulus (US).

Inferences regarding the learning of the CS-US relationship can be made from various skeletal, autonomic, or visceral responses of the subject to the CS. In the direct procedure, the CS is presented to the subject at an arbitrary time, and some response change is noted. For example, to determine if a subject has learned the relationship between a tone (CS) and a shock (US), the tone may be sounded alone and the change in heart rate recorded. Either an increase or a decrease in rate (relative to appropriate control groups) is evidence that the subject has learned the relationship between the CS and the US.

Alternatively, an indirect procedure may be used to determine if a subject has learned the relationship between the CS and the US. In the conditioned emotional response (CER) procedure, the subject is trained to perform an instrumental response. Either in the same or in separate sessions, it also receives a noxious stimulus at the termination of an experimenter-controlled stimulus, and then the CS is presented to the subject at an arbitrary time while it is performing the instrumental response. For example, the subject may be trained to obtain food pellets or avoid shock by pressing a lever, and then the change in the rate it presses a lever is noted during presentation of a tone that has had its termination associated with shock. If the subject is pressing the lever for food reinforcement, the tone generally produces a reduction in response rate; if the subject is pressing the lever to avoid shock, the tone generally produces an increase in response rate. Either an increase or a decrease in the response rate (relative to appropriate control groups) is evidence that the subject has learned the relationship between the CS and US.

TABLE 16.1 CLASSIFICATION OF THE BASIC INSTRUMENTAL TRAINING PROCEDURES WITH NOXIOUS STIMULI

	Correlation of event with response	
Event	*Positive*	*Negative*
Onset of Noxious Stimulus	Punishment	Avoidance
Termination of Noxious Stimulus	Escape	Preservation

Instrumental Learning

In aversive instrumental learning the onset or termination of a noxious stimulus is contingent upon a response. There are four clearly distinguishable procedures, and three of them have well-established names (see Table 16.1). In the "punishment" procedure the onset of a noxious event is positively correlated with a response; for example, a lever response by a rat is followed by a brief shock. In the "avoidance" procedure the onset of a noxious stimulus is negatively correlated with a response; for example, a lever response prevents or postpones the occurrence of a shock. In the "escape" procedure the termination of a noxious stimulus is posi-
Figure 16.3. Classification of the basic procedures for the study of aversive behavior. See text.

tively correlated with a response; for example, a lever response turns off a shock or reduces its intensity. Logically, there is the alternative of the "preservation" procedure in which the termination of a noxious stimulus is negatively correlated with a response; for example, as long as the rat presses the lever, the shock continues. In all cases of instrumental learning, the task for the subject is to learn the relationship between a response and its consequences. Inferences may be made regarding this learning from (a) the proportion of opportunities on which the subject makes the response, (b) response speed, or (c) choice behavior.

A Classification of the Basic Procedures

Of course, there is an underlying continuum between a perfect positive correlation and a perfect negative correlation, and this is illustrated in Figure 16.3. A point in the lower right-hand corner represents the ideal punishment procedure (the probability of a shock given a response is 1.0, and the probability of a shock given a nonresponse is 0.0). A point in the upper left-hand corner represents an ideal avoidance procedure (the probability of a shock given a response is 0.0 and the probability of a shock given a nonresponse is 1.0). The diagonal between these points would represent a continuum of procedures between punishment and avoidance. A point in the lower left-hand corner would represent the usual extinction procedure (that is, the probability of getting shock is zero regardless of whether a response is made or not), but the entire diagonal from the lower left-hand corner to the upper right-hand corner represents conditions under which the event (shock onset) is independent of response. The degree of dependence can be represented by the index $(X - Y)/(X + Y)$ where X is the probability of a shock given a response and Y is the probability of a shock given a nonresponse. By this definition, any two points that lie on a straight line whose origin is zero are equivalent in the degree of dependence. For example, the index of dependence is +1.0 for all points on the horizontal axis, 0.0 for all points on the drawn diagonal, and − 1.0 for all points on the vertical axis.

Of course, two procedures that are equivalent with respect to the dependence of shock upon a response are not necessarily equivalent with respect to the probability of a shock given a response. For example, partial punishment occurs when the index of dependence is 1.0, but the probability of shock given a response is less than 1.0. Most research on the acquisition of aversive behavior has concentrated on the cases in which the dependence was +1.0 (punishment) or −1.0 (avoidance); most research on the elimination of aversive behavior has concentrated on a single procedure of nondifferential reinforcement—extinction by omission of the noxious stimulus.

Although Figure 16.3 represents the punishment-avoidance case, if the event were shock termination instead of shock onset, it would represent the escape-preservation case. The lower right-hand corner would represent the usual escape procedure, that is, the probability of shock termination given a response would be 1.0 and the probability of shock termination given a nonresponse would be 0.0. The upper left-hand corner would represent the preservation procedure. All points on the drawn diagonal would represent cases in which shock termination is independent of a response (Overmier & Seligman, 1967).

To represent various cases of classical conditioning, the event could remain shock onset (US), but this event would be conditional upon an experimenter-controlled stimulus (CS) rather than a response. Thus any point below the drawn diagonal would involve explicit association of CS and US, and the lower right-hand corner would represent the usual classical conditioning procedure, that is, the probability of shock onset given a stimulus would be 1.0 and the probability

of shock onset given no stimulus would be 0.0. Any point above the drawn diagonal would involve explicit disassociation of the CS and US (Rescorla & LoLordo, 1965). Any point along the diagonal would involve independence of CS and US, and a point in the lower left-hand corner would represent the usual extinction procedure.

Most studies of aversive behavior necessarily involve both classical conditioning and instrumental learning. During a study of classical conditioning the response to the experimenter-controlled stimulus should not affect the nature of the noxious event in any way. Nonetheless, the effect of the puff of air used for classical eyelid conditioning may be different if it hits the open rather than the closed eye; the effect of acid on the tongue used in classical salivary conditioning may be different if the tongue is moist with saliva than if it is dry; the effect of an electric shock used in classical leg-flexion conditioning may be different if the leg is already flexed than if it is extended. Although, in a study of classical conditioning, the behavior of the subject does not influence the experimenter's presentation of the unconditioned noxious stimulus, it may influence the effective intensity of noxious stimulus. Furthermore, in any study of instrumental learning in which a discriminative stimulus is used, there is a relationship between the experimenter-controlled stimulus and the noxious event as well as between a response and an event. For example, if in the presence of a discriminative stimulus a response is followed by a brief electric shock, the subject may decrease its responses in the future either because of the relationship between (1) the stimulus and the noxious event, or (2) the response and the noxious event.

Noxious events may also be presented as a function of time from a stimulus, a response, or another event. All of these procedures will be called "temporal conditioning." Finally, noxious events may be presented in a particular environment randomly with respect to stimuli, responses, and time. Such independent presentation of noxious stimuli will be described as the "noncontingent" procedure, although the events are associated with situational stimuli.

CONDITIONED FEAR

If a noxious event (for example, an electric shock) is contingent upon an experimenter-controlled stimulus (for example, a tone), a subject may become afraid when the tone occurs. In this example, the tone is a conditioned stimulus (CS) or warning signal for the unconditioned stimulus (US) of inevitable shock. This procedure is designed for classical conditioning of fear. Four types of testing procedures have been used to assess the effects of the classical conditioning of fear: (1) direct measurement of elicited autonomic and skeletal responses, (2) conditioned emotional response, (3) acquired drive, and (4) secondary punishment. In the direct procedure the CS is presented at an arbitrary time, and elicited autonomic or skeletal conditioned responses are recorded. In the conditioned emotional response procedure, a subject is trained to perform an instrumental response, and a CS is presented at an arbitrary time. Evidence for a learned association between the CS and the US would be a change of the response rate during the CS greater than that of appropriate control groups. In the acquired drive procedure a specified response terminates the CS; in the secondary punishment procedure a specified response produces the CS. An increase in responding in the acquired drive procedure or a decrease in responding in the secondary punishment procedure is evidence for the acquisition of fear.

The conclusions from these studies of the classical conditioning of fear closely resemble the conclusions of Pavlov that were based on classical salivary conditioning (Pavlov, 1927). In the studies of salivary conditioning the US was food placed in the mouth of a dog (for the alimentary reflex) or acid placed in the mouth of a dog (for the defense reflex). In studies of fear conditioning the US normally

is electric shock. Presumably, any stimulus that the animal can perceive may become a conditioned stimulus in either salivary or fear conditioning. Although optimal performance may occur in eyelid and leg flexion conditioning only if the CS precedes the US by a fraction of a second (Woodworth & Schlosberg, 1954), classical fear conditioning and classical salivary conditioning are readily obtained when the interval between CS and US is in the order of minutes. Apparently, the laws of fear conditioning are identical to the laws of salivary conditioning (Maier, Seligman, & Solomon, 1969).

Furthermore, the laws apply not only to a basic principle of acquisition and extinction, but also to the detailed observations of the formation and inhibition of conditioned responses such as the following:

1. *Acquisition of a conditioned response.* If an experimenter-controlled stimulus (S) is repeatedly followed by an unconditioned stimulus (US), it will become a conditioned stimulus (CS+) that will elicit a conditioned response (CR).

2. *Acquisition of a secondary conditioned response.* If an experimenter-controlled stimulus (S) is repeatedly followed by a CS+, it, too, will become a CS+ that will elicit a CR.

3. *Failure of backward conditioning.* If an experimenter-controlled stimulus (S) and a US are in close temporal contiguity, but in the wrong order, that is, the US precedes the S, the S will not become a CS+. On the contrary, it will become an inhibitory stimulus (CS−). (An inhibitory stimulus is one which, when presented in combination with a CS+, reduces the magnitude of the CR more than an equivalent novel stimulus.) (See Fig. 14.2).

4. *Experimental extinction.* If a CS+ is no longer followed by a US the magnitude of the CR will decrease and, eventually, there will be "extinction below zero," that is, the experimenter-controlled stimulus will become an inhibitory stimulus (CS−).

5. *Differential inhibition.* If S_1 is repeatedly followed by a US, and S_2 is not followed by a US, S_1 will become a CS+, and S_2 will become a CS−.

6. *Conditioned inhibition.* If S_1 is repeatedly followed by a US, and a compound stimulus involving S_1 together with another stimulus ($S_1 + S_2$) is not followed by a US, S_2 will become a CS−.

7. *Inhibition of delay.* If S_1 is followed by a US only after a period of time, the temporal stimuli, shortly after the onset of S_1, will become inhibitory.

8. *External inhibition.* If a novel stimulus is presented during the application of a CS+, the magnitude of the CR will be decreased.

9. *Disinhibition.* If a novel stimulus is presented during the application of a CS−, the magnitude of the CR will be increased.

10. *Induction.* If a CS+ is preceded by a CS−, then the magnitude of the CR will be greater than if the CS+ is preceded by another CS+. The increase in the CR produced by the preceding CS− is called "positive induction." If, on the other hand, a CS− is preceded by a CS+ the CR will be less than if the CS− is preceded by another CS−. The decrease in the CR produced by the CS+ is called "negative induction."

11. *Generalization.* The greater the similarity between an experimenter-controlled stimulus (S) and a CS+, the greater the magnitude of the CR to S (generalization of excitation). The greater the similarity between S and CS−, the greater the inhibitary property of S (generalization of inhibition).

Direct Measurement of Elicited Autonomic and Skeletal Responses

A noxious stimulus elicits a complex set of autonomic and skeletal responses. For example, in the rat, a brief electric shock of sufficient intensity elicits gross motor responses, which may be recorded on a stabilimeter. The responses increase in magnitude as shock intensity is increased (Hoffman, Fleshler, & Abplanalp, 1964). If a relatively weak shock is given, the flinch response predominates, but as the intensity of the shock is increased, jump responses begin to predominate (Kimble, 1955). The probability of vocalization increases as the intensity of the shock increases (Blanchard & Blanchard,

1966). If a dog is given a brief electric shock of sufficient intensity his heart rate increases; also he displays exophthalmic reactions, pupillary dilation, and other autonomic responses (Black, Carlson, & Solomon, 1962).

Predictable reactions are also made following the shock. For example, the termination of an electric shock results in a marked decrease in the heart rate far below the baseline, a phenomenon that has been termed "relief" (Church et al., 1966). Following the termination of shock a subject may remain immobile for long periods of time.

Various emotional states are accompanied by gross cardiovascular changes in heart rate, blood pressure, and so on. Although the association of a previously neutral stimulus (CS) with a noxious stimulus (US) results in the conditioning of all of these responses, typically only the heart rate is monitored. Changes in the heart rate have sometimes been assumed to be an index of "fear," although these changes can also be produced by changes in skeletal movement and breathing.

The presentation of a tone (CS) followed by a shock (US) to a restrained dog rapidly leads to a conditioned increase in the heart rate; presentation of the CS without the US rapidly leads to extinction (Church & Black, 1958). Evidence for inhibition of delay also was reported from the experiment, that is, the latency of the maximum increase in the heart rate was approximately half the interval between CS onset and US onset, under both trace and delayed conditioning situations.

The results of classical conditioning of the heart rate parallel those of salivary conditioning. In the case of heart rate, however, it is possible to get a direct measure both of excitation and inhibition because the heart can beat either faster or slower than a control rate, whereas in the case of salivation, although excitation leads to salivation it is not possible for the amount of secretion to fall below zero (Gantt, 1960).

In the normal subject it is impossible to determine whether the classical conditioning procedure led "directly" to heart rate changes
Figure 16.4. Acquisition of a discriminative conditioned heart rate response in a curarized dog. Note that the magnitude of the response to CS+ was greater than to CS−, and that the response to CS− approached 0. (After Black, Carlson, & Solomon, 1962.)

or whether some skeletal mediation was responsible for the results. For example, a CS that is followed by a US could lead to breathing changes or to skeletal movement (for example, struggling) that could be reflected in the measured heart rate change (Smith, 1954). To eliminate such mediating responses, a number of experimenters have conditioned the heart rate response of dogs under curare-like drugs (for example, *d*-tubocurarine chloride). These muscular relaxants block the junctions between nerves and the striped muscles; with a sufficient dosage, they cause a flaccid paralysis. Despite the lack of all voluntary movement, the subjects apparently suffer no loss of consciousness (Smith et al., 1947) and dogs under curare can still learn.

Figure 16.4 shows the simple acquisition of a conditioned response and a discriminative conditioned response by one curarized dog. (The CS+ was followed by shock; the CS− was not followed by shock.) During the CSs the subject cannot change his breathing pattern because he is paralyzed. (He must, of course, receive artificial respiration.) He does not manifest any overt movement, and even an electromyograph record (EMG) may not indicate change in muscle tension during the CS (Black & Lang, 1964; Black, 1965). Nonetheless, conditioned responses and discriminative conditioned responses do occur.
Figure 16.5. The conditioned emotional response of rats. Note the decrease in response rate during the 5-min auditory stimulus during the 4 successive sessions. T = tone, S = shock. (After Estes & Skinner, 1941.)

Conditioned Emotional Response

One method for the quantitative assessment of anxiety is known as the conditioned emotional response (CER). The reference experiment was performed by Estes and Skinner (1941). Twenty-four rats were trained to press a lever on a 4-minute fixed-interval schedule of reinforcement (a schedule on which the subject received a pellet of food for the first response after each 4-minute interval). After 2 weeks of 1-hour sessions, the subjects were responding at a fairly constant overall rate with local cyclic effects produced by the temporal discrimination of the reinforcement schedule. During each of the next 6 sessions there were 2 presentations of an auditory stimulus, each of which lasted for 3 minutes and terminated with shock. Of course, reduction in the rate of bar pressing did nothing to postpone shock or reduce it. During the first session with the tone-shock pairings the number of responses made during the period of the tone was approximately the same as the average number made during the same fraction of the hour in control experiments, but gradually the subjects began to respond more slowly during the warning signal that was followed by inevitable shock. On subsequent sessions a single 5-minute presentation of the tone was terminated with a shock. Figure 16.5 shows the average cumulative number of responses as a function of time for the 6 subjects with highest response rates during the first 4 sessions with the 5-minute tone. The major result is that subjects markedly decreased their response rates during the presentation of the warning signal. The magnitude of this decrease is frequently regarded as an index of the degree of anxiety. It is thought that the emotional responses elicited by the auditory stimulus somehow interfered with bar pressing. Estes and Skinner (1941) also noted that the magnitude of suppression of bar pressing during the tone (1) increased as a function of sessions, and (2) remained fairly constant throughout the duration of the 5-minute tone. With a substantially greater number of pairings, however, there may be some recovery from the response suppression, and there may be some temporal discrimination (inhibition of delay) during the tone.

Although various autonomic and skeletal

responses may also be made to the CS during a CER experiment, they do not necessarily precede the response suppression (de Toledo & Black, 1966). The CER procedure has provided more complete and reliable information than any of the other methods regarding the determinants of conditioned fear.

The measure of response suppression In the CER experiment of Estes and Skinner (1941) the response rates of the subjects decreased considerably during the tone. The response suppression that takes place during the tone can be readily seen in the cumulative record, but relating the magnitude of the suppression to various independent variables requires a quantitative measure of the suppression. The major consideration in choosing a measure of the effectiveness of a treatment should be its sensitivity to the effects of the treatment. In other words, the measure of the behavior of subjects given any particular treatment should be similar, but the measure of the behavior of subjects given different treatments should be substantially different. An increase in the size of the sample can compensate for any lack of sensitivity in a measure, although, of course, if a more sensitive measure can be used, considerable gains in precision can be made without increase in experimental effort.

Perhaps the simplest measure would be the absolute response rate during the tone. Because there are marked individual differences in the response rate under any particular schedule of reinforcement, however, the rate during the tone does not necessarily reflect the influence of the tone. Whenever there is a substantial correlation between the performance prior to treatment and that during (or following) treatment, as in the case being discussed, some measure of the change will be more sensitive to treatment differences than an absolute measure. Perhaps the simplest combination of the response rate prior to treatment (A) and the response rate during treatment (B) is the difference ($A - B$). In practice, however, most investigators make use of one of the ratio measures. For example, Stein, Sidman, and Brady (1958) used B/A; Hoffman and Fleshler (1961), $(A - B)/A$; and Annau and Kamin (1961) $B/(A + B)$. The range from complete suppression to none at all would be zero to 1 for B/A; 1 to zero for $(A - B)/A$; 0 to .5 for $B/(A + B)$. Measures that are linearly related [for example, B/A and $(A - B)/A$] are necessarily identical in sensitivity. The measure of suppression that is used must be noted carefully before attempting to read a figure based on one of the ratio measures.

The basic procedure for assessing the sensitivity of a measure has been described by Hays (1963), and it has been applied to extensive data from punishment research by Church (1969). The ratio measures for the punishment data were substantially more sensitive to treatment effects than the response rate alone (B) or the difference in response rate ($A - B$).

In many situations a psychologist may choose among various alternative measures of the effectiveness of a treatment. For example, we may use the time taken by a rat to traverse a runway (running time) or its reciprocal (running speed); we may measure the skin resistance (in ohms) or its reciprocal, skin conductance (in mhos). We may use the actual frequency count or the square root or logarithmic transformation of this count. If an arithmetic operation is applied to each of a set of numbers that are recorded by some device, the original numbers are transformed. A measure may be chosen because it can be read directly from standard recording devices, or because it produces scores which may be distributed in a fashion that meets the assumptions of standardized statistical tests. Of course, a measure also may be chosen because it is well established by precedent. The major consideration, however, is the amount of information any measure conveys about a treatment.

Intensity of the unconditioned stimulus
The speed of acquisition of the CER and the magnitude of the suppression is a function of the CS, the US, and the relationship between them. A series of studies by Kamin and his colleagues has provided a detailed parametric analysis of these variables. The procedure used in the study of the effect of the intensity of the US (Annau & Kamin, 1961) can serve as the reference for the general procedure. Groups of 8 experimentally naive rats were used as subjects. They were placed on a restricted food schedule that reduced their weight to approximately 75 percent *ad libitum* weight. Then they were trained to press a lever on a 2.5-minute variable-interval schedule of food reinforcement for at least 10 hours. They were then given a series of 2-hour sessions in which the food reinforcement was continued, and, in addition, a CS of white noise was presented for four 3-minute periods. During the pretest session no shock was given, but during the
Figure 16.6. The conditioned emotional response as a function of US intensity. The suppression ratio was $B/(A + B)$, where B = response rate during CS, and A = response rate prior to CS. (After Annau & Kamin, 1961.)

next 10 sessions each CS was terminated simultaneously with the delivery of a US of .5 second duration. Each group received a different intensity of the foot shock, the intensities being about .28, .49, .85, 1.55, or 2.91 mA.

Following the 10 sessions of conditioning, 10 sessions of (Pavlovian) extinction were given, during which the treatment was continued, but without foot shock. The dependent measure was a suppression ratio, $B/(A + B)$, where B is the number of responses during the 3-minute interval of the CS and A is the number of responses during the 3-minute interval prior to the CS. The results show that the greater the intensity of the US, the greater the magnitude of response suppression during conditioning (Figure 16.6). At an intense US (.85 mA and above) there was nearly complete suppression by the second conditioning session. At an intermediate level of intensity (.49 mA) there was partial suppression, followed by recovery of the response rate. At the mildest level of intensity used (.28 mA) there was no detectable suppression, although the intensity produced an obvious flinching response. This intensity, however, was sufficient to suppress a response in the presence of a discriminative stimulus when each response was followed by the noxious stimulus (the punishment procedure).

Disinhibition The presentation of noxious stimuli to a subject while it is responding for food reinforcement may result in a decrement in response rate. At high intensity and at a rapid rate of presentation, particularly if the noxious stimuli are unsignalled, there may be considerable response suppression. When a novel stimulus is presented during response suppression, disinhibition results, in other words, there is an increase rather than a decrease in response rate during the signal (Brimer & Kamin, 1963). This increase in response rate to a novel stimulus was particularly marked in subjects whose response rate was most suppressed by the unsignaled shocks. If subjects were given additional sessions of training without shock, so that their response rate was no longer suppressed, prior exposure to the shock had no residual effect on the response to the novel stimulus. Of course, presentation of a novel stimulus to a subject that has simply been trained to perform an instrumental response will result in a decrement in the response rate (external inhibition). Brimer (1963) has demonstrated, however, that the presentation of a novel stimulus will result in an increase in the response rate if the response previously has been inhibited by a number of different variables (extinction, satiation, free shock, and so on). This procedure provides a method for exploring Pavlovian disinhibition.

Temporal relationship between conditioned stimulus and unconditioned stimulus Most of the research on the CER has employed a delayed conditioning paradigm, that is, the CS remained on during the CS-US interval. A trace conditioning procedure is one in which the CS terminates prior to the onset of the US. Kamin (1961) demonstrated that

this procedure is also adequate to produce response suppression. In that study, with the interval between the onset of the CS and the onset of the US constant at 3 min (the CS-US interval), the greater the length of the CS (that is, the shorter the trace interval) the greater the magnitude of response suppression. In the case of subjects with a 2-min CS followed by a 1-min trace, suppression developed during the trace interval and remained specific to that interval.

Although the "association span of the white rat" (Warner, 1932) depends upon the procedure that is used for measurement, it is clear that suppression can occur when an interval in the order of minutes separates CS onset or termination from US onset. Nonetheless, the magnitude of the response suppression is greater if a delayed conditioning procedure is used than it is if a trace conditioning procedure is used, particularly if the interval between CS onset and US onset is long. Even an extremely brief half-second time gap between the termination of the CS and the introduction of the US can greatly reduce the magnitude of response suppression (Kamin, 1965).

As in the case of Pavlovian salivary conditioning, backward conditioning does not occur (see pp. 557; 710). For example, using procedures similar to those of his previous experiments, Kamin (1963) found that rats did not reduce their rate of lever pressing during a 3-min white-noise CS that immediately followed the termination of a 0.5-sec shock US.

Intensity of the conditioned stimulus The rapidity of conditioning is positively related to the intensity of the CS (Kamin & Schaub, 1963). This result implies either that an intense CS is more effective than a weak CS (stimulus intensity dynamism) or that a large stimulus change is more effective than a small stimulus change (discrimination hypothesis). To distinguish between these two hypotheses, comparisons have been made between CSs of various increments in intensity to 80 dB (70–80, 60–80, 50–80, 45–80 and 0–80) and CSs of various decrements in intensity from 80 dB (80–70, 80–60, 80–50, 80–45 and 80–0). The results indicated that the greater the stimulus change, and the greater the physical intensity contiguous with the US (that could not be separated from the direction of change in this experiment), the greater the magnitude of suppression. Although this function is present when delayed conditioning procedures are used, it is particularly marked when the trace conditioning procedure is used (Kamin, 1965). Similar results for pairs of stimuli differing in intensity have been obtained by Sadowski (1966) under conditions where one stimulus was paired with food reinforcement and the other stimulus was paired with omission of food.

Generalization If a subject is conditioned to one stimulus, the maximum suppression occurs to that stimulus, but suppression also occurs to a range of similar stimuli (generalization). The magnitude of suppression to a stimulus is closely related to the physical similarity between it and the one involved in the original CER conditioning. For example, Ray and Stein (1959) presented a high-frequency tone with shock and a low-frequency tone without shock (discrimination training) and found that intermediate frequencies produced intermediate suppression. Similarly, Hoffman (1965) trained pigeons to peck a key and then adapted them to a 2-minute variable-interval schedule of food reinforcement. The birds then were given pairings of a 1000 Hz tone and shock during food-reinforced sessions. After the degree of suppression had stabilized, they were tested with frequencies above, at, and below the 1000 Hz tone while responding on the schedule of food reinforcement. None of the tones during the tests were followed by shock. Figure 17.8 (p. 759) shows the suppression for one subject to various stimulus frequencies (tones) as a function of trials of testing. Note that the generalization gradient became narrower as extinction proceeded.

The generalization gradient also was narrower for pigeons that had undergone a high degree of deprivation (70 percent *ad libitum* weight) than for pigeons with lower degree of deprivation (80 percent *ad libitum* weight).

Relative duration of the conditioned stimulus In most studies of the CER a CS 3 to 5 minutes in duration is presented no more often than once or twice in an hour. If the CS is on during only a small percentage of the session, for example, less than 10 percent of the time, the absolute duration of the CS does not appear to affect the magnitude of suppression (Kamin, 1965). For example, if a subject with a 2-min or 3-min variable-interval schedule of reward suppresses completely during the CS, it loses relatively few reinforcements. If the CS occurs during a large percentage of the session, the subject would lose many reinforcements if it suppressed completely during the signal. Stein, Sidman, and Brady (1958) varied the duration of the CS and the interval between CS presentations, and they found that the log of the relative duration of the CS (and, therefore, the percentage of reinforcements that would be missed if the subject did not respond during the CS) was linearly related to the magnitude of suppression (Figure 16.7). The implication of this result is that a subject is more likely to suppress during a signal if such suppression does not involve the loss of reinforcements. Alternatively, the results might be interpreted as indicating greater conditioning of the CER if the interval between trials is long relative to the duration of the CS. Such results would be quite consistent with studies of the interval between trials using food reinforcement.

Figure 16.8. The conditioned emotional response and differential inhibition. Response rate prior to the CSs, during CS_1 that had previously been followed by a US, and during CS_2 that had previously (in combination with CS_1) been predictive of a period of safety. (After Rescorla & LoLordo, 1965.)

Figure 16.7. The conditioned emotional response as a function of percentage of reinforcements that would be lost if suppression were complete. The suppression ratio was B/A, where B = response rate during CS, and A = response rate prior to CS. (After Stein, Sidman, & Brady, 1958.)

Effect of the conditioned emotional response on avoidance behavior Although the presentation of a CS that has been followed by a noxious stimulus will lead to a decrease in the response rate of a rat pressing a lever for food reward, it will lead to an *increase*

in the rate of a monkey pressing a lever to postpone shock (Sidman, Herrnstein, & Conrad, 1957). This result was replicated and extended by Rescorla and LoLordo (1965) who trained dogs to postpone shock for 30 seconds by jumping from one side of a shuttlebox to the other. In separate sessions, the dogs were confined to one side of the shuttlebox and given presentations of a 5-second CS_1 followed either by a shock or by CS_2. Under these conditions, CS_1 would be expected to elicit fear responses, and CS_2 to inhibit the fear responses (conditioned inhibition). A test session was then run in which CS_1 and CS_2 were presented for 5 seconds each without respect to the dogs' behavior, and without any shocks (an extinction procedure). Figure 16.8 shows that, relative to the pre-CS rate, CS_1 resulted in an increase in response rate and CS_2 resulted in a decrease. As in the experiment by Sidman, Herrnstein, and Conrad (1957), a CS that is followed by shock increased the rate of avoidance responding, presumably because it increased fear. In addition, the conditioned inhibitor (CS_2) decreased the rate of avoidance responding, presumably because it decreased fear. Rescorla and LoLordo (1965) also demonstrated differential inhibition: If CS_1 was followed by shock, a CS_2 that was not followed by shock decreased the rate of avoidance responding. Finally, they demonstrated that in a situation with unsignaled shocks with CS_2 guaranteeing a period of safety, CS_2 also decreased the rate of avoidance. Further research with the same general procedures has demonstrated inhibition of delay, inhibition from backward conditioning, and positive and negative induction (Maier, Seligman, & Solomon, 1969). Such observations demonstrate that Pavlovian inhibitory processes, like Pavlovian excitatory processes, may be investigated by the CER procedure.

This final result is of methodological importance with respect to a pseudoconditioning-control group. If a subject is more responsive to a CS after it has been paired several times with a US, there is still the question of whether the unpaired presentation of the CS and the US would not have led to a similar result (pseudoconditioning). One way to set up a control is to present the same CS and US given to one group of subjects to another group of subjects, but without allowing the US to follow shortly after the CS. The argument for this procedure would be that if the conditioning group (with CS and US paired) were more responsive than the pseudoconditioning control group (with CS and US explicitly unpaired), the conditioning group must have developed an association between the CS and US (an excitatory process) as a result of the pairing. Unfortunately, a difference between the two groups could also result from a disassociation of CS and US (inhibitory conditioning) in the group used as a control for the pseudoconditioning with explicitly unpaired presentations of CS and US. To eliminate the contingency between CS and US the random presentation of CS and US would be the appropriate control for pseudoconditioning (Rescorla, 1967). (This will lead to occasional pairings of CS and US, but the conditional probability of a US given a CS will be equal to the overall probability of a US, that is, the two events will be independent.)

Acquired Drive

If a noxious stimulus is given in one particular location, a subject can learn to perform some response to escape from that location. The reference experiment was reported by Miller (1948). Rats were trained to escape from shock in a white compartment by running through an open door into a black compartment. The animals continued to run from the white compartment into the black compartment during the 5 trials on which no shock was given. The major problem was to determine whether a subject would learn to perform a new response in order to escape from the white compartment. During the next 16 trials the door between the two compartments was closed, but the subject could
Figure 16.9. Acquired drive. The mean latency of the wheel-rotation response decreased as a function of trials. Rotation of the wheel opened a door that permitted the rat to leave the white compartment (in which it had been shocked) and to enter the black compartment. (After Miller, 1948.)

open the door by rotating a wheel a small fraction of a turn. Thirteen of the 25 animals turned the wheel on 4 or more of the first 8 trials. The response latency of these subjects decreased as a function of trials (Figure 16.9). The situation was changed for the next trials, so that the wheel could not be used to open the door; rather, using a lever would do so. The median number of turns on the wheel decreased to zero, and the average speed of pressing the lever increased as a function of trials. As a result of the escape training, subjects learned to be afraid in the white compartment and the black compartment acquired secondary reinforcing properties (Lawler, 1965). If the subject makes a response (for example, running, turning a wheel, or pressing a lever) that permits it to terminate the cues for fear, it will learn to make that response, and the reinforcement may be called "fear reduction" or "termination of stimuli associated with noxious stimulus." Some of the early experiments with this procedure are summarized by Miller (1951).

The acquired drive procedure has not been used widely for the evaluation of Pavlovian conditioning because (1) a situational stimulus is used rather than one controlled by the experimenter; (2) if the subject does not "accidentally" perform the arbitrarily selected response rapidly, the repeated or long pres-
Figure 16.10. Secondary punishment. *Left:* Schematic representation of the five different arrangements of the 3-sec CS and the 10-sec US. In Group 5 the CS occurred 2-min after US termination. *Right:* Mean number of responses per minute of rats in the five groups. Each response produced food reinforcement and a flashing light (secondary punishment) that had previously been followed by electric shock (US). (After Mowrer & Aiken, 1954.)

entation of the CS leads to the extinction of fear; and (3) the duration of the exposure of the subject to the stimuli is not under the experimenter's control.

Secondary Punishment

The secondary punishment procedure has also been used to derive the general principles of acquisition of fear. Mowrer and Aiken (1954), for example, used this procedure to evaluate the role of the temporal relationship between the CS and the US in fear conditioning. Fifty rats were trained in one compartment to press a lever for food reinforcement (20 responses, each followed by a food pellet), and then they were placed in another compartment for fear conditioning. The CS was a 7.5 W light that flickered at the rate of 4 Hz, and the US was an electric shock of 165 VAC (with 175,000 Ω resistance in series). Ten subjects were assigned to each of five groups (Figure 16.10, left panel). The CS occurred either during the 3 seconds preceding the US, the first 3 seconds of the US, the last 3 seconds of the US, 3 seconds following the US, or 2 minutes following the US. On the next 5 days the subjects were allowed to make 5 food-reinforced responses in one compartment, and they later received one fear-conditioning trial in the other compartment. Finally, on the test session each subject was allowed to press the lever for food for 5 minutes and then, for the last 25 minutes of the session, each response was followed not only by food, but also by a 3 second presentation of the CS. The results are shown in Figure 16.10, right panel. In all groups there was a decrease in the response rate followed by some recovery, but the magnitude of the decrease was greater in groups in which the CS preceded or overlapped the beginning of the US than in groups in which the CS followed or overlapped the end of the US. This experiment was replicated by Matsumiya (1960), who extended the study to three shock intensities (.2, .4, and .6 mA). The .2 mA shock produced no effective secondary punishing effect with any pattern of CS and US, but with the .4 and .6 mA shocks, the results of Mowrer and Aiken (1954) were replicated. These results are consistent with the conclusion that the greater the intensity of the US, the greater the effectiveness of a previously neutral stimulus as a secondary punisher.

It should be noted that studies of this type require careful preliminary investigations to determine appropriate shock levels, amounts of training, levels of deprivation, and so on, to insure that some, but not complete, suppression of the response is produced.

Fear is developed to a CS as a result of the onset of a noxious stimulus, not its termination. Mowrer and Solomon (1954) compared groups with two durations of US (3 and 10 sec) and two conditions of shock termination (abrupt and gradual). The CS for all groups occurred during the 3 sec preceding the onset of the US. The effectiveness of the CS as a secondary punisher was equivalent in all groups, a result that implied that the conditions of onset rather than of termination of the noxious stimulus are critical for the establishment of conditioned fear. Of course, as Mowrer and Solomon pointed out, if the US were very short it would be less effective for producing fear than a shock of longer duration because it would be less severe.

In Mowrer's procedure, the test session introduces no shock, and when a CS is no longer followed by a US, it gradually loses its secondary punishing function. To avoid this extinction effect Hake and Azrin (1965) described a procedure for concurrently maintaining a secondary punishment and a test of its effectiveness. A pigeon was trained to peck a key on a 2-min variable-interval schedule of food reinforcement, and each response produced a 5-sec CS. To develop and maintain the secondary punishment, the pigeon was occasionally given a 15-sec CS followed by a 100-msec shock, the pairings occurring on the average, once every 6 minutes. Under

these conditions, there was evidence of a conditioned emotional response (a reduction in response rate during the CS) and secondary punishment (a reduction in response rate in the absence of the CS).

In general, studies of secondary punishment have found that subjects respond more slowly (1) during the warning signal (a conditioned emotional response), (2) prior to the onset of a warning signal because a response may produce a warning signal (anticipation of the CS), and (3) following a warning signal (reaction to the CS). While the experimental literature gives us some clues as to what factors are controlling suppression, at present, knowledge of the basic mechanisms is far from complete.

ESCAPE

Consider the following situation: A rat is placed in the starting compartment of a straight alley that consists of a start box, a 4-ft runway, and a goal box. When the guillotine door is opened a shock begins on the floor of the start box and alley, but not in the goal box. When the rat reaches the goal box a guillotine door is lowered to prevent retracing, and the rat is removed from the apparatus. On the first trial the rat reaches the goal in 5 seconds. Oddly enough, most rats will have a somewhat longer escape latency on the second trial, but in 20 or 30 trials the subject normally reaches or exceeds a speed of 4 ft/sec.

In general terms, the escape training procedure is one that involves the presentation of a noxious stimulus that the subject can reduce or eliminate by an appropriate instrumental response. The escape response may involve moving through an apparatus such as a straight alley or a one-way shuttlebox or, to eliminate intertrial handling, a circular alley or a two-way shuttlebox; it may require manipulating an object in the apparatus such as a lever, a wheel, or a panel, or moving a particular limb.

Because an escape response occurs following each presentation of the noxious stimulus, response latency or response speed are the usual dependent variables, and learning is inferred from the reduction of latency or an increase in speed as a function of trials.

Acquisition

Escape learning follows the general laws of learning of instrumental responses for positive reinforcement.[2] Asymptotic performance is a function of the magnitude of reinforcement (relative reduction of shock intensity), the delay of reinforcement (delay of shock termination), and the percentage of responses reinforced.

Magnitude of reinforcement If the response terminates the shock, the asymptotic running speed is positively related to shock intensity, at least through a considerable range of intensity (Trapold & Fowler, 1960). In one experiment 30 rats were trained to escape from shock in an alley consisting of a start box (8 inches long), an alley (48 inches), and a goal box (12 inches). Each subject was given 20 trials of training during a single session. The starting time (to the nearest .01 sec) was measured from the raising of a guillotine door until the subject broke a photobeam 6 inches down the alley. The running time (also to the nearest .01 sec) was measured from the time that the subject broke this photobeam until he broke another photobeam located 2 inches inside the goal

[2]Some reinforcements consist of the onset of a stimulus; others consist of the termination of a stimulus. These have been called "positive reinforcement" and "negative reinforcement," respectively. Food has been called a "positive reinforcer" because its presentation to a hungry animal has been demonstrated to increase the frequency of a preceding response; electric shock has been called a "negative reinforcer" because its termination has been demonstrated to increase the frequency of a preceding response. Thus the "positive" and "negative" refer to the increase or decrease in the magnitude of the reinforcing stimulus. This distinction between positive and negative reinforcement is arbitrary in the case of some reinforcing stimuli. For example, if a change from temperature *X* to temperature *Y* is reinforcing, one may equally well say that the onset of *Y* is a positive reinforcer or the termination of *X* is a negative reinforcer. The fact of fundamental importance for behavior is whether the stimulus change is reinforcing, neutral, or punishing.
Figure 16.11. Mean escape latency and speed as a function of intensity of the noxious stimulus. (After Trapold & Fowler, 1960.)

box. These times were converted to speed scores (ft/sec) and the results, averaged across the 6 subjects in each group and for the last 8 trials of training, are presented in Figure 16.11. Running speed increased as a function of shock intensity, but starting speed increased with shock intensity up to 240 V (250,000 Ω in series) and then decreased with further increases in intensity. High intensity shock apparently elicits responses that are incompatible with short starting latency, perhaps causing the subject to jump or producing muscle tetany. Throughout most of its range, however, increasing shock intensity leads to an increase in speed, presumably because the level of drive is higher, or the reduction of the noxious stimulus is greater.

The level to which the shock can be reduced is an important determinant of escape performance, even when the shock intensity from which subjects are escaping is kept constant. Bower, Fowler, and Trapold (1959) trained rats to run from an alley where they were shocked with 250 V to a goal box where they were shocked by 50 V, 150 V, or 200 V. The speed of the subject was related to the voltage of the goal box, and when the intensity of the shock in the goal box was changed there was a rapid change in the speed of the subject appropriate to the new level of shock. A comparison of the speed of rats that were changed to a particular condition with those maintained on that condition provided no suggestion of a contrast effect (Figure 16.12).

It would not be correct, of course, to assume that the reinforcing value of an escape

Figure 16.12. Median escape speed as a function of the intensity of the noxious stimulus in the goal box. Shock in the start box and the alley was 250 V. (After Bower, Fowler, & Trapold, 1959.)

response would be accurately measured by the reduction in the absolute number of volts produced by the response. Presumably, the Weber-Fechner relationship, investigated thoroughly in psychophysical studies of stimulus discrimination, would at least be approximated roughly in studies of escape learning. On the basis of this hypothesis, Campbell and Kraeling (1953) compared the reinforcing value of a reduction of 100 V when the initial value was 400, 300, or 200 V. They found that asymptotic running speed was a function of the reduction in shock relative to the initial level and not to the absolute reduction in shock intensity (see Figure 16.13).

In an extension of the research described above Campbell (1956) found the reduction in voltage necessary for a rat to choose the lower voltage in a tilt cage 75 percent of the time. He found that as the intensity of the noxious stimulus is increased, the absolute reduction in intensity necessary to produce a just noticeable difference increases (Figure 16.14).

Delay of reinforcement If the escape response is reinforced by a reduction in shock intensity when the subject reaches the goal compartment, then the asymptotic performance should be a function of the immediacy of the shock termination. This experiment has been performed by Fowler and Trapold (1962). In six different groups, termination of a shock intensity of 240 volts occurred immediately after a rat reached the goal compartment or 1, 2, 4, 8, or 16 sec after the rat reached the goal compartment. Figure 16.15 shows that the longer the delay before the shock is terminated, the lower the running speed.

Percentage of responses reinforced If termination of the noxious stimulus is the reinforcement for escape learning, is it conceptually possible for an experimenter not to provide reinforcement on a series of trials? Nonreinforcement would be nontermination
Figure 16.16. Mean escape speed on Trials 13–20 as a function of percentage reinforcement. Reinforcement was immediate termination of the shock; nonreinforcement was a 20-sec delay of shock termination. (After Bower, 1960.)

of the shock, but the subject must sometime be removed. In practice, a relatively long (such as 20 sec) delay of shock termination is considered nonreinforcement. As shown in Figure 16.16, the greater the percentage of responses that are reinforced, the greater the mean speed (Bower, 1960).

In a free-responding situation subjects readily learn to perform instrumental responses for schedules of positive reinforcement far less than 100 percent. If termination of a noxious stimulus is analogous to presentation of a positive reinforcement, then subjects should learn to make an instrumental response under various schedules of shock termination (fixed and variable interval, fixed and variable ratio, differential reinforcement of low response rates, and so on). Some investigators (for example, Winograd, 1965) have obtained evidence that schedules of positive reinforcement and schedules of termination of noxious stimulation lead to similar patterns of behavior. However, the competing responses elicited by electric shock are a major source of interference and preclude investigations of all but relatively short interval and ratio schedules. A noxious stimulus that does not elicit such marked incompatible responses would be required to demonstrate the essential similarity between the presentation of a reward (positive reinforcement) and the removal of a noxious stimulus (negative reinforcement).

Differential reinforcement of quantitative aspects of the escape response Various qualitative and quantitative aspects of the escape response may be explicitly taught by means of differential (correlated) reinforcement. For example, the speed of the escape response, like other quantitative and qualitative characteristics, can be specifically selected (Logan, 1960). If subjects are given immediate shock termination for reaching the goal slowly (for example, in more than 2.5 seconds) but long-delayed shock termination for reaching the goal quickly, these subjects typically learn to respond just slower than the arbitrarily selected criterion (much slower than otherwise). In one experiment, in which reinforcement was correlated with a slow response, rats learned to reach the goal at a sufficiently slow speed to gain reinforcement in more than 90 percent of the trials (Bower, 1960).

Prior exposure to inescapable shock A number of investigators have found that a series of inescapable shocks profoundly retards the development of subsequent escape behavior. For example, Dinsmoor and Campbell (1956) compared the escape performance of rats that had received a 15-min period in the apparatus, with or without a .2 mA inescapable shock. During a 35-min session of lever-response escape training (with an interval from shock termination to next shock onset of 20 sec) the group with prior exposure to shock made significantly fewer escape responses than the group without such prior exposure. Such interference may be a result of learning incompatible responses, adapting to shock, massive parasympathetic reaction, or learning the inde-

pendence between a response and shock termination.

Overmier and Seligman (1967) found that prior exposure to inescapable shock markedly interfered with subsequent shuttlebox escape learning, even if the subjects were curarized during the prior exposure to prevent the development of competing skeletal responses. Even if an extremely high (6.5 mA) shock was given during escape training, it did not overcome the interference effect. It is possible that during prior exposure to inescapable shock the subject learns the independence of shock termination and responding, that is, he learns that he is helpless (Maier, Seligman, & Solomon, 1969).

Extinction

Omission of reinforcement What is the procedure for the "extinction" of an escape response? By definition, omission of the reinforcement for a response is the procedure for extinction. If termination of the noxious stimulus is the reinforcement for escape learning, the procedure to bring about the extinction of an escape response would be to continue the shock (or, at least, to provide a long delay of shock termination).
Figure 16.17. Extinction of escape as a function of percentage reinforcement. Reinforcement was immediate termination of the shock; nonreinforcement was a 20-sec delay of shock termination. (After Bower, 1960.)

Although such studies are rare, presumably the same factors that contribute to resistance to extinction of an appetitive response contribute to the resistance to extinction of an escape response. For example, as we see in Figure 16.17, groups of rats that had been trained with immediate shock termination on 50 percent of the trials in a runway (partial reinforcement) had greater resistance to extinction than subjects that had been trained with immediate shock termination on 100 percent of the trials (Bower, 1960).

Omission of noxious stimulus Most studies of "extinction" of an escape response have omitted the noxious stimulus whether the subject made the response or not (for example, Sheffield & Temmer, 1950). Suppose a rat were placed in the starting compartment of a straight alley, the door opened, but no shock presented regardless of the behavior of the subject. This is an extinction procedure from the point of view of classical conditioning, for the unconditioned stimulus (reinforcement) of shock no longer follows the conditioned stimulus of the rising gate. This is an adequate procedure for the elimination of the escape response because (1) the absence of the noxious stimulus results in (a) the classical extinction of fear, (b) a decreased motivational level, and (c) generalization decrement; and (2) there is no differential reinforcement (that is, shock reduction) for performing the instrumental escape response. Omission of a noxious stimulus may also produce extinction of secondary escape, that is, extinction of escape from a stimulus that has been paired with a noxious event.

Punishment extinction The previous two procedures for the elimination of an escape response (omission of reinforcement of the instrumental response and omission of the noxious stimulus) were similar in that they provided nondifferential reinforcement, that is, terminating the shock was independent of the response. Explicit punishment of an

escape response, however, may lead to even more rapid elimination of the response than mere omission of the noxious stimulus (Seward & Raskin, 1960). Paradoxically, however, under some conditions punishment of an escape response may lead to an increase in the response speed and an increase in the number of trials necessary to reach a criterion of extinction (Gwinn, 1949; Brown, Martin & Morrow, 1964). This has been called "vicious-circle behavior" because the behavior leads to punishment that leads to an increase in response speed, and so on. It has also been called "masochistic" or "self-punitive" behavior because the rat appears to seek the noxious stimulus. Brown (1969) has reviewed the relevant studies and described the conditions under which punishment of an escape or avoidance response is most likely to increase resistance to extinction. Self-punitive behavior often occurs if the conditions of punishment extinction are similar to the conditions of escape training, and the response elicited by the shock and the response that terminates the shock are similar to the escape response.

Figure 16.18. Diagram of a shuttle box with swinging door separating the two compartments.

AVOIDANCE

Consider the following situation: A dog was placed in one side of a shuttlebox having two similar compartments (see Figure 16.18). Every 3 minutes the gate separating the two compartments was raised and the lights in the compartment in which the subject was confined were turned off (a compound warning signal CS). If the subject failed to jump across the barrier separating the two compartments within 10 seconds a shock was turned on. Both signal and shock terminated when a subject eventually entered the other compartment; such a response is called an *escape*. If, in contrast, the subject moved to the other compartment within 10 seconds after the onset of the signal, the signal terminated and no shock occurred. Such a response is called an *avoidance*. (If no response occurred within 2 minutes, both signal and shock were terminated.)

The behavior of a fairly typical subject during the procedure described above is given by Solomon and Wynne (1953): On the first trial the subject showed a general investigatory response at the onset of the signal, but when the shock went on, the subject began to move about the compartment vigorously and to manifest considerable emotional upset (vocalization, urination, defecation). Eventually, by chance, the subject jumped across the barrier to the other compartment, a response that resulted in escape from the shock and termination of the signal. Within a few trials the subject became motionless at the onset of the signal, perhaps with signs of emotionality. When the shock went on the subject rapidly moved into the other compartment (escape). A few trials later, when the signal occurred, the subject moved into the other compartment (avoidance), the signal termi-
Figure 16.19. Acquisition of an avoidance response as a function of trials. Latency on successive trials for a single dog. (After Solomon & Wynne, 1953.)

nated, and the shock did not go on. During subsequent trials of training the proportion of avoidance responses increased and the latency of the avoidance responses decreased (Figure 16.19). The important determinants of the acquisition and maintenance of such discriminative avoidance behavior have been summarized by Brush and Solomon (1956) and Hoffman (1966).

Acquisition of the Avoidance Response

Conditioned fear Any avoidance learning situation that involves a warning signal (S+) provides the opportunity for the development of conditioned fear.[3] Two-process theories of avoidance learning emphasize the distinction between the conditioning of fear to the signal and the consequences of an instrumental avoidance response (for example, Schlosberg, 1937; Mowrer, 1947). The conditioned fear presumably serves a critical role in the development and maintenance of the avoidance response. A systematic review of evidence relevant to two-process theories of avoidance learning has been provided by Rescorla and Solomon (1967).

The development of conditioned fear can be monitored during avoidance learning by measuring heart rate changes in the presence of an S+ (Black, 1959), but the interpretation of such data is complicated by the influence of gross motor movements on the heart rate. During the course of avoidance learning most subjects appear to learn to be afraid of the warning signal within a few trials, but eventually they learn to perform the avoidance response in an automatic and matter-of-fact manner. (A danger signal on a boiler dial is not likely to produce great emotion in a man who has learned a simple instrumental response to prevent an explosion, unless the response is blocked.)

Because the heart rate is dependent, in part, upon gross motor responding, an independent measure of fear is necessary to support the notion that fear increases and then decreases during the course of avoidance learning. One such measure is the conditioned emotional response (CER), and it has provided tests of the course of fear during avoidance learning (Hoffman & Fleshler, 1962; Kamin, Brimer, & Black, 1963). In the experiment by Kamin and his coworkers, rats were trained to press a lever on a 2.5-min variable-interval schedule of food reinforcement, and then were given trials of avoidance learning in a shuttlebox, with a 20-sec interval between S+ and shock. Independent groups were given trials until they reached a criterion of 1, 3, 9, or 27 avoidance responses. They then were returned to the lever box for further training,

[3] The warning signal in an avoidance learning situation is often called a conditioned stimulus (CS+). In this chapter the terminological convention has been adopted to call a signal a conditioned stimulus (CS+) if the noxious stimulus is independent of any instrumental response, and to call the signal a discriminative stimulus (S+) if the noxious stimulus depends, at least in part, upon some instrumental response.

but now there was a 20-sec S+ presented on the average of once each 4 minutes. The magnitude of the suppression of bar pressing after the subject was exposed to an S+ was a U-shaped function of the number of avoidances in the shuttlebox; that is, the maximum suppression occurred with intermediate criteria. The initial training trials were almost always escape trials, with S+ followed by shock. Therefore, additional trials of avoidance training initially increased the magnitude of conditioned fear because they resulted in an increase in the number of classical conditioned fear acquisition trials.

The magnitude of suppression of subjects that received 1, 3, 9, or 27 classical pairings of CS and US in the shuttlebox was an increasing function of the number of pairings. Eventually, however, additional trials of avoidance training may decrease the magnitude of conditioned fear since each successful avoidance is an extinction trial for conditioned fear; S+ is not followed by the shock. (The magnitude of the suppression of subjects that received extinction of avoidance responding in the shuttlebox to a criterion of 0, 5, or 20 failures to avoid was a decreasing function of the criterion.) The decrease in the magnitude of conditioned fear during avoidance training may also have been a consequence of the formation of conditioned inhibition. The S+ and a response was never followed by the shock, and the S+ without the response was always followed by the US. Therefore, the response (a subject-produced stimulus) could serve as a conditioned inhibitor of fear. If the response were blocked, the latent fear would be manifested (Solomon, Kamin, & Wynne, 1953).

Emergence of the avoidance response In the case of a response that is followed by positive reinforcement, most theories of learning make no attempt to account for the emergence of the first response. When it occurs, however, the principles of classical conditioning and instrumental learning are used to account for the selective strengthening or weakening of specific responses in the presence of specific stimulus configurations. In the case of avoidance learning, however, some attempts have been made to account for the emergence of the first avoidance response. Before they make the first avoidance response, most subjects have developed conditioned fear to the S+, and they have learned to escape rapidly from the shock. A substitution theory, that S+ becomes equivalent to the shock, would imply that the latency of the first avoidance response to an S + typically would be as short as the escape response to the shock. However, if the first avoidance response had a latency nearly as long as the interval between S + and shock, the response might be regarded as an escape response that had "moved backward in time." Neither position is strongly supported by the data.

As in the case of a positively reinforced response, any factor that increases the general level of spontaneous activity (for example, deprivation conditions) will increase the rate of most responses that are arbitrarily selected to be the active avoidance response. In addition, the treatment on the escape trials is crucial. A subject will learn an avoidance response more rapidly if (1) it has had prior escape learning (Church & Solomon, 1956), (2) the same response is used for avoidance as for escape (Mowrer & Lamoreaux, 1946), (3) the noxious stimulus terminates at the time of the escape response rather than, say, 5 sec afterwards, and (4) the S+ terminates at the time of the escape response rather than at shock onset or 5 sec after the escape response (Kamin, 1959; Kamin et al., 1959).

Reinforcement of the avoidance response Escape responses are reinforced by termination of the noxious stimulus, but what reinforces avoidance responses? Inasmuch as such responses result in termination of the warning signal, and prevent the occurrence of the noxious stimulus, it is reasonable to ask if one or both of these consequences of the avoidance response

might reinforce it. Since, during trials on which the subject escaped (but had failed to avoid), the warning signal had been followed by the noxious stimulus, there should be formation of conditioned fear to the warning signal. Termination of such an experimenter-produced signal could produce relief from fear, and thus it could serve as the reinforcement of the avoidance response. On the other hand, a response during the warning signal guarantees a long interval without a noxious stimulus, so that stimuli produced by that response could become safety signals and thus serve as the reinforcement of the avoidance response. Kamin (1956) compared the effects of response termination of the warning signal and prevention of the noxious stimulus on avoidance learning. Under the "classical" procedure a trial consisted of a 5-sec CS followed by a US, from which the subject could escape. In the "avoid shock" procedure, a response did not affect the S+ but it did prevent the occurrence of the shock. In the "terminate signal" procedure, a response did not affect the shock but it did terminate the S+. In the "normal" procedure a response both terminated the S+ and prevented the occurrence of the shock. The results are shown in Figure 16.20. Both termination of the warning signal and avoidance of the shock increased the percentage of avoidance responses, and decreased the response latency.

Figure 16.20. Two sources of reinforcement of an avoidance response. Percentage of avoidance responses for groups in which a response during the signal (1) avoided the shock, (2) terminated the signal, (3) both avoided the shock and terminated the signal (normal), or (4) neither avoided the shock nor terminated the signal (classical). (After Kamin, 1956.)

Determinants of Avoidance Learning

The warning stimulus Not all stimuli that are discriminable are equally effective as a warning signal in avoidance learning. In general, an intense, complex stimulus with a sudden onset is particularly effective for rapid acquisition (Myers, 1960). But with any warning signal termination is one of the sources of reinforcement of avoidance learning, and delay of termination of the S+ decreases the level of performance. In one experiment Kamin (1957) demonstrated that the percentage of avoidance responses of rats, each with 100 trials in a single session, was inversely related to the interval between response and termination of the warning signal (0, 2.5, 5.0, and 10.0 sec). Stimuli that have become CS+ and CS− on the basis of discriminative classical conditioning can control subsequent avoidance responses (Solomon & Turner, 1962).

The noxious stimulus Although the magnitude of conditioned fear is positively re-

Figure 16.21. Avoidance responses as a function of shock intensity. (After Moyer & Korn, 1964.)

lated to the intensity of the noxious stimulus, high intensities of electric shock interfere with the acquisition of the avoidance. For example, Moyer and Korn (1964) found that the percentage of avoidance responses of rats in a shuttlebox decreased as shock intensity increased (Figure 16.21).

The percentage of avoidance responses made by rats in a lever box is greater if a shock is used that is moderate and pulsating than if a shock is used that is intense and continuous (D'Amato & Fazzaro, 1966), although a higher level shock may be superior for the maintenance of avoidance behavior after it has been acquired (D'Amato, Fazzaro, & Etkin, 1967). Apparently high-intensity shock elicits motor responses (for example, freezing) that are incompatible with instrumental avoidance responding. If an extremely low shock intensity is used, of course, the mean response latency is long (Kimble, 1955) and few subjects learn the avoidance response (Brush, 1957).

Interval between the warning stimulus and the noxious stimulus Early studies of the interval between warning stimulus and shock in avoidance learning arose from an interest in the "span of association" (Warner, 1932). The studies have shown that rats can successfully learn an avoidance response if the interval between the onset of the S+ and the onset of the shock is 20 seconds or more. (A much longer association span has been demonstrated with the CER technique.) The major finding of these experiments is that the longer the interval between the S+ and the shock the longer the mean avoidance latency, both in the case of delayed and trace conditioning (for example, Church, Brush, & Solomon, 1956). This result is presumably closely related to the "inhibition of delay" in classical conditioning described by Pavlov (1927). An increase in the interval between the warning signal and the shock results in an increase in the latency of classically conditioned responses and avoidance responses in various species, for example, the fish (Bitterman, 1965) and the dog (Church & Black, 1958). Of course, the mean avoidance latency would be related to the interval between the warning stimulus and the noxious stimulus, even if the response were emitted randomly in time (because only the longer intervals could contain long latency responses). Analysis of the conditional probability of responses of various latencies, and of the response latency on the first extinction trial, however, suggest that if the subject has a short interval between signal and shock he is maximally responsive sooner than if he has a long interval between signal and shock. Thus the possibility that the relation of the interval between S+ and shock on the one hand and avoidance latencies on the other is merely an artifact of the procedure can be dismissed: Subjects apparently learn when to respond as well as how to respond in avoidance situations.

The relationship between the rate of avoidance learning and the interval between the S+ and the noxious stimulus is complex. In different studies the mean number of trials to criterion has been found to vary directly with the interval (Kamin, 1954), to be independent of the interval (Brush, Brush, & Solomon, 1955), and to be inversely related to the interval (Behrend & Bitterman, 1962). The problem is that the "mean number of trials to criterion" reflects not only the degree of association between S+ and the noxious stimulus, but also the opportunity to respond (Bitterman, 1965). Thus a subject exposed to a 20-sec interval between S+ and noxious stimulus has a greater opportunity to make an avoidance response than a subject allowed only a 5-sec interval. If subjects are trained at different intervals, and then are tested at the same relatively long intervals, the opportunity for avoidance responses is equalized (although the magnitude of generalization decrement is not). Such a transfer design has led to the conclusion that the rate of acquisition of avoidance response to a delayed S+ is roughly equal across intervals from 1 to 60 seconds.

Pseudoconditioning If, under the conditions of avoidance training, a subject per-

forms the instrumental response to the conditioned stimulus, does this imply that the subject has learned the association between the S+ and the shock? If the subject had been given the opportunity to escape from the S+ before the beginning of avoidance training, and it had failed to do so, this would be evidence that the S+ was not initially a noxious stimulus. After a number of presentations of the shock, however, the subject may perform the instrumental response to the S+ whether or not it had been followed by the shock. The shock may serve to predispose the subject to react to almost any stimulus, and when a frightened subject is startled by any novel stimulus it may accidentally perform the instrumental response, and thus the termination of the novel stimulus may reinforce this behavior. Many examples of pseudoconditioning have been reported (for example, Smith, McFarland, & Taylor, 1961), and it occurs more readily with buzzers than with physical stimuli that are easier to specify (pure tones, white noise, lighted panels). The random presentation of S+ and shock in a pseudoconditioning control group may lead to a higher state of anxiety than the signaled presentation of the shock in the avoidance conditioning group. At least, subjects prefer a signaled to an unsignaled shock in a choice experiment (Lockard, 1963). (See also p. 578.)

Failures of acquisition Many experimenters have reported difficulty in training rats to perform a discriminative avoidance response in a lever box. Such failures are not rare. Typically, these subjects become alert and hover at the lever when the signal is turned on and then, when the shock is turned on, they press the lever rapidly (escape). Despite the fact that they have demonstrated a clear association of the S+ with the shock, and have learned an instrumental act to the shock, they do not learn to perform the avoidance act (for example, Meyer, Cho, & Wesemann, 1960). The major difficulty is that the warning signal causes the subject to "freeze." Thus, if a drug that increases mobility (for example, amphetamine) is administered, the rate of avoidance responses is increased.

Subjects can be trained to press a lever to avoid a shock, if the shock is mild and pulsating, but training the subjects to press a lever is more difficult than training them to run away from the stimulus (in a shuttlebox). This observation is not merely a peculiarity of rats, for although the conditions are otherwise the same, the particular response that is chosen for avoidance will be an important determinant of the rate of learning and the asymptotic performance of any species. Turner and Solomon (1962), for example, reported that human subjects in a traumatic avoidance learning situation failed to learn to avoid a shock significantly more often if a short-latency, reflexive movement were required than if a longer-latency, gross motor movement were required.

Even after a subject is performing an avoidance response with a high probability, he may stop doing so in some subsequent trials (Coons, Anderson, & Myers, 1960). This phenomenon has been replicated under a number of conditions, but it has not been adequately explained.

Nondiscriminative Avoidance

Any avoidance learning situation that does not involve a warning signal may be called "nondiscriminative avoidance." That is, a subject can learn to make an instrumental response to postpone a noxious stimulus even if there is no experimenter-controlled stimulus (S+). Furthermore, a subject can learn to make an avoidance response even if there is no possibility of escape from the noxious stimulus. This procedure has been extensively investigated by Sidman (1953, 1966), and it is often called "Sidman avoidance." A representative situation is the following: When a rat makes a lever response it postpones the occurrence of shock for 20 seconds. (This minimum interval between the response and the shock is called the "R-S interval.") If the rat fails to press the lever within 20 seconds a brief (.2-sec) shock is given, and it reoccurs
Figure 16.22. Rate of avoidance responding as a function of the response-shock (R-S) and the shock-shock (S-S) intervals. (After Sidman, 1953.)

every 5 seconds. (This interval between the onset of one shock and the next is called the "S-S interval.") A response during the S-S interval returns the subject to the R-S interval. Under this condition, if a subject responds at least once each 20 seconds it will avoid all shocks. The mean response rate of one subject under various S-S and R-S intervals is shown in Figure 16.22. After initial nondiscriminative avoidance training this subject received a series of 3-hour sessions at a particular R-S and S-S interval. The criterion of stability was a difference in rate not greater than 0.1 response per minute between the third hour of 2 out of 3 consecutive sessions. After the criterion was met, another value of the R-S interval was used. After all the R-S values had been used at one S-S value, they were repeated in another order at another S-S value. Under these conditions, as the R-S interval decreased the response rate gradually increased to some maximum value, and then declined abruptly. The R-S interval that resulted in the maximum rate was positively related to the S-S interval.

If the R-S interval were made shorter than half the S-S interval a subject responding randomly in time would actually increase the frequency of shocks received (Sidman, 1966). This may be the primary factor accounting for the decline in the response rate when the R-S interval is made short relative to the S-S interval (the falling of the curves to the left of the maxima). The longer the R-S interval is made, the lower the frequency of shocks received, and because many subjects made a burst of responses following a shock under this condition, the reduction in shock frequency may have been the primary factor accounting for the gradual decrease in the response rate as the R-S interval increased (the falling of the curves to the right of the maxima). On the other hand, this function may reflect a temporal discrimination (that is, if the subject responded shortly before each shock was due, the longer the R-S interval was made, the lower the response rate would be). Although the temporal discrimination may emerge as a function of repeated training, the acquisition of the avoidance response may depend primarily upon a reduction of shock density. Just as a subject may change his response rate when the S-S interval is changed from zero minutes (continuous shock) to 2 minutes between shocks, so may a subject change his response rate when the S-S interval is shifted from an average of 9 shocks per minute to an average of 3 per minute (Herrnstein & Hineline, 1966). This implies that the same principle that was used to account for the acquisition of escape behavior can be extended to account for some cases of avoidance behavior. The reinforcement of an escape response is reduction in the severity of a noxious stimulus. If shock density (frequency per unit time) as well as intensity and duration of a shock is a determinant of severity, then avoidance behavior in the absence of a warning signal, like escape behavior, may be reinforced by reduction of the severity of a noxious stimulus.

In contrast to most subjects used to study the nondiscriminative avoidance procedure in the shuttlebox, those placed in the lever box usually do not show an obvious temporal discrimination. However, examination of the conditional probabilities of interresponse times often reveals some temporal discrimination (Anger, 1963). A subject with a 20-sec
Figure 16.23. Temporal discrimination in Sidman avoidance. The probability of a response given the opportunity for a response increased as the time from the last response increased. (After Anger, 1963.)

R-S interval has the opportunity to make a response between 0 and 1 sec after the last response each time it responds, but it has the opportunity to make a response between 19 and 20 sec after the last response only on those rare occasions that it has waited for 19 sec. Therefore, evidence for a temporal discrimination is provided by the conditional probability of a response (the probability of a response given the opportunity for a response—the IRTs/opp). The distribution of the conditional probability of a response of one subject with an excellent temporal discrimination under conditions of 20-sec R-S interval and a 20-sec S-S interval is shown in Figure 16.23 (Anger, 1963). The conditional probability of a response was an increasing function of the time since the last response.

Extinction of Avoidance Responses

The usual extinction procedure for avoidance is omission of the shock. Thus, for extinction of discriminative avoidance behavior, if the subject responds within the signal-shock interval used in training, the treatment is identical to that used during training (that is, the signal terminates and the shock does not occur). If the subject fails to respond within the signal-shock interval, however, the treatment during extinction differs from that used during training (that is, the signal terminates and the shock does not occur).

If the conditions of avoidance training produce a subject that always performs the avoidance response, by definition, it should continue to respond during extinction indefinitely. Extremely high resistance to extinction has been reported for some cases of avoidance learning. For example, Solomon, Kamin, and Wynne (1953) reported that dogs that had met a criterion of 10 avoidance responses on a session of training failed to extinguish the responses during the next 20 sessions of 10 trials per day. In fact, over 99 percent of the responses were made within 10 seconds of the S+ onset; also during the sessions the mean latency continued to decrease despite the absence of any shock.

However, it would not be correct to say that avoidance responses are more resistant to extinction than responses reinforced by food. A subject may be trained to make an instrumental response during a 10-sec stimulus to receive food reinforcement at the end of the stimulus. Such a subject would have an extremely high resistance to extinction, if the extinction procedure consisted of presenting the food at the end of the stimulus, whether or not the subject made the response. Furthermore, in many cases of avoidance learning, omission of the noxious stimulus without prompt termination of S+ results in fairly rapid extinction (Kamin, 1954; Katzev, 1967).

Resistance to extinction is decreased if a subject is prevented from making the instrumental response during the early trials of extinction. One way to prevent a subject from making a previously learned avoidance response is to administer a massive dose of *d*-tubocurarine chloride, or a similar drug, to produce a flaccid paralysis. Such a subject can develop conditioned fear to the S+, but it cannot move. Black (1958) demonstrated that the amount of extinction produced by 50

trials of S+ without shock was greater if the subject was prevented from making the instrumental response than if it were not.

PUNISHMENT

Consider the following situation: A rat is placed in a box that contains a retractable lever, a food cup, and a grid floor that can be electrified. On the average of once each 3 minutes a tone begins, and the lever is automatically inserted into the box. If the subject presses the lever within 10 seconds, a small pellet of food is automatically dropped into the food cup, the tone ceases, and the lever is withdrawn; if the subject fails to press the lever within 10 seconds the tone stops and the lever is withdrawn, but no food is delivered. If the animal is hungry, and if it is not frightened, this procedure is sufficient to teach the subject to press the lever.[4]

After the rat learned to press the lever reliably and quickly, a punishment procedure was begun. On the first trial under the changed conditions, the tone began, the lever was inserted into the box, and (in about 2 seconds) the subject depressed the lever. On this occasion the subject received a brief electric shock through the grid floor, and a pellet of food was dropped into the food cup. The subject squeaked and jumped back, and then it approached the food cup and ate the pellet of food. On the next trial the tone again began and the lever was inserted, but this time the response latency was much longer (about 7 seconds). Again the rat received both the punishing and the positive reinforcing events. About 3 minutes later the next trial occurred, and the rat failed to respond within 10 seconds. No response was made on any of the next 20 trials, and the experiment was terminated.

Punishment, in this example, clearly led to a suppression of the instrumental lever-pressing response, but there are numerous alternative explanations regarding the mechanism through which it exerted this effect. First of all, there are the *situational cues* of the box with its grid floor and food cup. Second, there are the *experimenter-controlled* stimuli of the tone and (since a retractable lever was used) of the lever. Third, there are the *response-produced* stimuli of the proprioceptive feedback of the lever-press response, and also of the visual and auditory consequences of the response. Finally, there are the *events* of presenting food to a hungry subject (positive reinforcement) and shock (punishment), both of which have obvious stimulus properties. The observed response suppression could have been a result of the association of the shock with the situational stimuli (generalized anxiety), the experimenter-controlled stimuli (CER), the response-produced stimuli, or any combination of these stimuli.

An explanation of the suppression produced by punishment requires, in addition to the identification of the relevant stimuli, a statement of the manner in which these stimuli affect behavior. According to a *fear hypothesis,* the subject becomes afraid and immobile in the presence of the stimulus and thus fails to make many responses, including the instrumental lever-pressing response. In some cases (for example, Hunt & Brady, 1955) the magnitude of suppression in the presence of a signal is similar whether the shock is inevitable (CER) or dependent upon a response (discriminative punishment). Alternatively, the subject may begin to make skeletal responses similar to those elicited by the onset of the punishment, which may interfere with its response of pressing the lever (the *competing response hypothesis*), or it may make skeletal responses similar to those it typically made at the termination of the punishment, which may also interfere with the lever-pressing response (the *escape hypothesis*). If the skeletal responses to the onset of

[4]To establish a stable level of hunger the subject should be maintained for several weeks on a schedule of restricted food intake, and to reduce fear the experimenter should handle the subject daily for several weeks.

punishment or its termination are compatible with the learned instrumental response, then punishment of a response might facilitate that response (Guthrie, 1952; Fowler & Miller, 1963).

According to the *avoidance hypothesis,* response suppression produced by punishment may occur for the same reason as response acquisition during avoidance learning (Dinsmoor, 1954). In the case of avoidance learning (sometimes called "active avoidance") a specified response prevents the noxious stimulus, but all other responses result in the noxious stimulus being given. In the case of punishment learning (sometimes called "passive avoidance") the opposite is true; that is, a specified response results in the presentation of the noxious stimulus, but all other responses prevent it. Similar principles may account for active and passive avoidance.

Thorndike's (1911) original interpretation of the effect of punishment on behavior may be called the *negative law of effect.* He stated that a noxious stimulus weakened a response tendency in a direct manner similar to the direct strengthening of a response tendency by a positive reinforcer (positive law of effect). Although he later abandoned this position (Thorndike, 1932) he apparently did so for insufficient reason, for at the present time the data on punishment are most conveniently organized around the negative law of effect (which is sometimes called the "suppression hypothesis").

Of course, the theories of punishment described above are not mutually exclusive. In fact, there is reasonably strong experimental evidence to indicate that each of them offers a partial explanation for the observed reduction in the tendency to respond (Church, 1963).

Determinants of Magnitude of Suppression

Punishment is a technique for the suppression of a response. In general, the effect of a response-contingent noxious event (a punishment) is opposite of the effect of a response-contingent reinforcing event (a positive reinforcement), and some of the same variables determine the magnitude of these opposite effects. For example, an intense punishment is more effective in suppressing behavior than a mild one, and a punishment is more effective in suppressing behavior if it is presented immediately after a response than if it is delayed by several seconds. The same variables of magnitude and delay of reinforcement influence the effectiveness of positive reinforcers for strengthening a response and presumably such parallels would exist with regard to other variables as well. Brief summaries of many of the relevant experiments are available (Azrin & Holz, 1966; Church, 1963, 1969).

Intensity The degree to which a response is suppressed is an increasing function of the intensity of the punishment. In one experiment (Karsh, 1962) groups of rats were trained for 75 trials to run to the end of an 8-ft alley for food reinforcement. Then each subject received 1 trial per day for 40 days during which both food and shock were given at the goal. The intensity of shock for the various groups was 0, 75, 150, 300, and 600 V for .1 sec, administered through 250,000 Ω in series with the subject. At the lowest intensity of punishment used (75V) the rats were indistinguishable from control subjects in their running speed, although the shock level was undoubtedly above a detection threshold so that it could be used as a cue. At intermediate levels of intensity there was partial suppression followed by a considerable recovery in the response rate, with the initial effect of the punishment on the early sessions far more pronounced than that on later sessions. At higher intensity of punishment there was partial suppression, without complete recovery, and at the highest level of intensity virtually total response suppression.

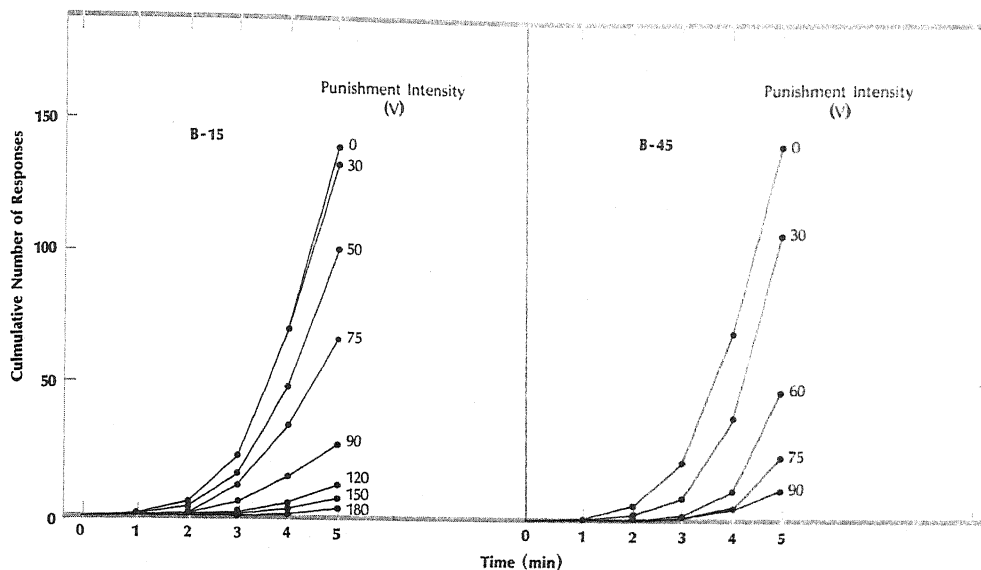
In another experiment (Azrin & Holz, 1961) two pigeons were trained to peck a response key with food delivered on a 5-min fixed-


Figure 16.24. Intensity of punishment. The cumulative number of responses of two pigeons receiving punishment of each response during fixed-interval food reinforcement. (After Azrin & Holz, 1961.)

interval schedule of reinforcement; they received a brief (.1 sec) shock following each peck. (The shock was administered through electrodes implanted in the tail region of the bird and the circuit had 10,000 Ω in series with the subject.) Under the fixed-interval schedule of reinforcement the birds developed a temporal patterning of responses such that they responded more rapidly as the end of the fixed interval approached. Although they maintained this temporal pattern under the conditions of punishment, the cumulative number of responses was inversely related to the punishment intensity (Figure 16.24). Thus, both under conditions of one trial per day and under conditions of free responding, the degree of response suppression was a function of the intensity of the punishment. If only a moderate intensity of punishment was administered, however, the magnitude of suppression decreased as a function of the increasing number of sessions of punishment.

Duration The effect of an increase in the duration of a punishment is similar to an increase in its intensity. If punishment of
Figure 16.25. Duration of punishment. Response suppression as a function of duration of punishment in seconds. The suppression ratio was $B/(A + B)$, where B = response rate on a session of punishment, and A = response rate on the final session prior to punishment. (After Church, Raymond, & Beauchamp, 1967.)
Figure 16.26. Mean speed of approach to food reinforcement of rats with gradual or sudden introduction of electric shock at the goal. (After Miller, 1960.)

moderate intensity is given for extremely brief periods of time, there will be no suppressive effect. As the duration is increased, however, there will be partial suppression with complete recovery, then partial suppression without complete recovery, and finally, total suppression without recovery (Church, Raymond, & Beauchamp, 1967).

In that experiment groups of rats were trained to press a lever for food pellets, delivered on a 1-min variable-interval schedule of reinforcement into which were inserted occasional punishing shocks with durations of 0.15, 0.30, 0.50, 1.00, or 3.00 sec. The mean suppression ratio, $(B/(A + B))$ with B = response rate on a particular session of punishment training and A = response rate on the final session prior to punishment training is shown in Figure 16.25. When the intensity as well as duration of the punishment was varied, the mean suppression ratio was a linear function of the logarithm of the product of the intensity and the duration of the punishment. Presumably, the intensity and duration of punishment jointly determine the severity of the punishment, and the magnitude of response suppression is a function of the severity of the punishment.

Prior exposure to the noxious stimulus
The magnitude of response suppression to a punishment is a function of the prior experience of the subject with the punishing stimulus. Miller (1960) demonstrated that rats may learn to resist the effects of pain and fear if the intensity of the punishment is only gradually increased. Figure 16.26 shows the results

from one experiment. Rats were trained to run to the goal box of an 8-ft alley for a wet morsel of food, about the size of a pea. When the subject touched the food it completed a circuit of subthreshold current that operated an electronic relay. This relay (*a*) stopped a clock for the running time, and (*b*) delivered a shock of .1 sec duration through 250,000 Ω in series with the subject on the punishment trials. After 75 trials of reward training half the subjects received a punishment of gradually increasing intensity (as well as a reward) and the other half received only the reward. After 75 trials of this differential treatment both groups received punishment of 335 V. The average speed of subjects with prior exposure to punishment of increasing intensity was reliably faster than that of subjects that had not had such exposure. Thus prior exposure to punishment of gradually increasing intensity attenuates the suppressive effects of subsequent punishment.

Other studies have shown that prior exposure to a single condition of punishment that is of low intensity, brief duration, low frequency, or long-delayed after a response, attenuates the subsequent response suppression produced by a punishment that is more intense, of longer duration, more frequent, or temporally closer to a response (Feirstein & Miller, 1963; Banks, 1966; Karsh, 1966; Church, 1969).

In contrast to the effects described above, there are some situations in which prior exposure to an intense electric shock can increase the effectiveness of a subsequent shock when it is used as a punishment (Walters & Rogers, 1963; Pearl, Walters, & Anderson, 1964). When prior exposure increases the effectiveness of subsequent punishment, the phenomenon may be labeled "sensitization," and when prior exposure decreases the effectiveness of subsequent punishment, the phenomenon may be labeled "adaptation" or "habituation," but such labels, of course, do not explain the results. In general it appears that prior exposure to a noxious stimulus of low severity minimizes the effects of subsequent noxious stimuli of greater severity, whereas prior exposure to a noxious stimulus of high severity increases the effects of subsequent noxious stimuli of less severity (Karsh, 1963). One interpretation is that there is a degree of behavioral inertia such that the suppression produced by punishment may be intermediate between the amount that would occur to that punishment in the absence of previous exposure to shock and the amount produced by the prior exposure.

Temporal relationship between response and punishment The extent that a response is suppressed by punishment is greater if the noxious stimulus follows immediately after the response than if it is delayed by several seconds. In the case of punishment of a shuttlebox avoidance response, Kamin (1959) demonstrated this delay-of-punishment gradient, showing that the shorter the temporal interval between response and punishment, the fewer the number of responses in extinction. Such a result is not a consequence of the temporal interval between the warning signal and the noxious event because it also occurs in the free-responding situation (Camp, Raymond, & Church, 1967).

Contingency between response and punishment A noxious stimulus may suppress the rate of an appetitive response even if it is not contingent upon a response (Estes, 1944; Camp, Raymond, & Church, 1967). However, if there is a positive correlation between the occurrence of the noxious stimulus and the occurrence of the response, the magnitude of response suppression will be greater.[5] For example, Azrin (1956) compared the response rates of pigeons under conditions of response-contingent and response-

[5] The dependence of a noxious stimulus (S) upon a response (R) may be represented as $[p(S|R) - p(S|\bar{R})]/[p(S|R) + p(S|\bar{R})]$. The degree of dependence (contingency) between a response and a noxious stimulus is a determinant of the magnitude of suppression, as well as the probability of the noxious stimulus per unit time $[p(S)]$ or the probability of a noxious stimulus given a response $[p(S|R)]$.

independent presentation of shock. During each session a pigeon received a 3-min variable-interval schedule of positive reinforcement. In the presence of one discriminative stimulus, only this reinforcement schedule was in effect; in the presence of the other discriminative stimulus, both positive reinforcement and an aversive stimulus were presented. The noxious stimulus was either contingent upon a *response* (scheduled to follow the first response after a fixed or variable interval from the onset of the discriminative stimulus) or it was independent of the response (scheduled to occur a fixed or variable *time* after the onset of the discriminative stimulus). The response rate of pigeons in the presence of the discriminative stimulus for noxious stimulation was lower in the case of contingent shock (punishment) than in the case of independent presentation of the noxious stimulus.

Punishment and Resistance to Extinction

Punishment serves to reduce the frequency of occurrence of some unwanted behavior, both during the period that it is being applied and after the punishment period has been completed. If the punishment is severe, the suppression of the behavior may be complete. For example, dogs may develop a profound inhibition of eating if they have been punished only a few times in the act of eating in a particular apparatus (Lichtenstein, 1950). A rat may starve to death rather than respond in a situation that produces food reward on half the trials and punishment on the other half (Klee, 1944).

In contrast, several studies seem to indicate that a brief period of mild punishment early in extinction does not reduce the total number of responses during regular extinction. These studies have employed as the "punisher" an event that was perhaps no more noxious than many other novel stimuli (Skinner, 1938), or a level of shock that did not produce reliable suppression even while it was being applied (Estes, 1944, Experiment A).[6] However, even a short period of moderate punishment early in extinction reduces the total number of responses during extinction (Estes, 1944; Boe, 1964; Boe & Church, 1967; Estes, 1969). Under one procedure rats were trained to press a lever during three 1-hour sessions of acquisition on a 4-min fixed-interval schedule of food reinforcement, and then were given successive daily 1-hour sessions of extinction (Estes, 1944; Boe & Church, 1967). During a 15-min period of the first extinction session (the fifth through the twentieth minute), subjects in the experimental group were given a brief electric shock contingent upon responses on a 30-sec fixed-interval schedule of punishment. (Thus, a subject would receive a maximum of 30 punishments if it responded at least once during each 30 sec of the 15 min punishment-period.) During the remainder of this first extinction session, and during the subsequent 1-hour extinction sessions, responses were neither

Figure 16.27. Permanent effects of punishment during extinction. The response percentage was $(B/A) \times 100$, where B = response rate on a session of extinction, and A = response rate on the final session prior to punishment. Punishment (P) was contingent upon lever pressing during minutes 5–20 of the first extinction session. (After Boe & Church, 1967.)

[6] Such results may have served as the basis for the widespread belief that punishment is an ineffective method for control of behavior. Solomon (1964) has questioned the empirical bases for this statement, as well as for the belief that intense punishment typically leads to neurosis.

reinforced nor punished. Figure 16.27 shows the cumulative response percentage (relative to the number of responses on the final session of acquisition) as a function of the source voltage of the punishment (150,000 Ω in series). Punishment produced both an immediate decrease in responding during the punishment period and a permanent decrease in responding during the nine sessions of extinction. The magnitude of both effects of punishment was related to the intensity of the punishment.

The Role of Punishment in Discrimination Learning

Early research on punishment attempted to compare the relative incentive value of reward and punishment (for example, Warden & Aylesworth, 1927). Thus a rat would be trained to enter the compartment of a discrimination box under one of three conditions: (1) Reward: The subject received food if correct and was removed from the apparatus if incorrect. (2) Punishment: The subject was simply removed from the apparatus if correct but received a punishment if incorrect. (3) Reward and punishment: The subject received food if correct and punishment if incorrect. The direct comparison of performance under conditions of reward alone or punishment alone has not been satisfactory, and probably the question has not yet even been formulated properly, for the punished subjects have no clear reason for entering either compartment. Nonetheless, such research has lead to the unequivocal conclusion that punishment of the incorrect response (in addition to reward of the correct response) leads to faster discrimination learning than merely reward of the correct response.

Although it agrees with common sense that punishment of the incorrect response should increase the rate of discrimination learning, it is not intuitively obvious that punishment of the correct response should sometimes have a similar effect, but this result
Figure 16.28. Cumulative number of errors as a function of trials for groups that received no shock, shock for the correct (reinforced) response, and for the incorrect (nonreinforced) response. (After Muenzinger, 1934.)

has been obtained. Muenzinger (1934) compared the rate of learning a two-choice visual discrimination task by rats that either were punished for the correct response (the one that was rewarded), were punished for the incorrect response (the one that was not rewarded), or were not punished for either response. The subjects that received the noxious stimulus learned the discrimination task more quickly than subjects that were not punished, and there was no significant difference between the cumulative number of errors of subjects that were punished for the correct response and those punished for the incorrect response (Figure 16.28). However, subsequent research by Muezinger and others (for example, Wischner, 1947) demonstrated, under a variety of conditions, that punishment for making an incorrect response increased the rate of discrimination learning more than punishment for making the correct response. In one experiment (Wischner,
Figure 16.29. Mean number of errors as a function of intensity of punishment for group that received shock for the correct response and group that received punishment for the incorrect response. (After Wischner, Fowler, & Kushnick, 1963.)

Fowler, & Kushnick, 1963), as the intensity of the punishment increased, the number of errors in the group punished for the correct response increased and the number of errors in the group punished for the incorrect response decreased (Figure 16.29). In these studies subjects punished for the correct response did not perform any better than the unpunished control group. Nonetheless, if the punishment is very mild and the task is relatively difficult (the two cues to be discriminated are similar) a group punished for the correct response will make fewer errors than an unpunished control group (Fowler & Wischner, 1965). Although there are a number of plausible explanations for this paradoxical effect of punishment, the major function of the punishment may be to increase the discriminability of the two stimulus alternatives (Fowler & Wischner, 1969), perhaps by slowing responding and thus increasing the time during which the discriminanda are exposed before a choice is made.

These studies demonstrate that punishment is not only a technique that contributes to the elimination of old modes of response but that it also contributes to the rapid acquisition of new modes of response. As a general rule, punishment is particularly effective for the suppression of a previously learned response if an alternative response is concurrently reinforced (Whiting & Mowrer, 1943). For that reason, in many practical situations, the most effective training techniques involve a judicious combination of reward and punishment.

REQUIREMENTS FOR A GENERAL THEORY OF AVERSIVE BEHAVIOR

At the present time there is no general theory of aversive behavior, but such a theory will undoubtedly emerge from the extensive research findings that have been published, particularly in the last 25 years. Such a theory should describe interrelationships among the following concepts:

Classical conditioning and instrumental learning. The principles required to account for the behavior resulting from contingencies between experimenter-controlled stimuli and noxious events (the classical procedures) may be similar to those required to account for the behavior resulting from contingencies between responses and noxious events (the instrumental procedures).

Avoidance, punishment, escape, and preservation. In this chapter the various instrumental procedures involving noxious events have been treated separately, but there are important interrelationships among them. A general theory of aversive behavior should reveal the essential continuity among them, and it should explore the cases that are intermediate between the ideal cases.

Negative and positive events. The principles required to account for the behavior resulting from events from which organisms avert may be similar to those required to account for behavior resulting from events they approach. A relativistic view would be that the behavioral result depends not solely upon the particular event (for example, a mild shock or a small bit of food) but that it is dependent upon the direction of change.

For example, an animal may approach a shock intensity of 0.1 mA if currently stimulated by a higher intensity, but may avoid a shock intensity of 0.1 mA if presently stimulated by a lower intensity. Although most general theories of learning (for example, Tolman, 1932; Skinner, 1938; Hull, 1943; Spence, 1956) have been based primarily upon evidence from instrumental procedures with positive events, presumably a general theory could equally well be made that is based on evidence from procedures with negative events.

A general theory of aversive behavior undoubtedly will evolve in two directions: "formal" and "physiological." A formal theory of aversive behavior involves a precise description of the input to and the output from a subject, but no consideration of events occurring inside its body. It would undoubtedly become increasingly quantitative, rather than verbal, and it might make considerable use of mathematical models and computer simulation. A physiological theory would necessarily make considerable use of the great advances in knowledge regarding the biological basis of behavior (neuroanatomy, neurophysiology, psychopharmacology, and behavioral genetics). It would make use of results of research on the brain (electrophysiological and chemical stimulation, recording, and lesions). Either type of theory could provide important guidance for further research on aversive behavior.

THE DISCRIMINATIVE CONTROL OF BEHAVIOR

17

THE NATURE OF DISCRIMINATIVE CONTROL

The study of discriminative control is concerned with the covariation of stimuli and responses from moment to moment. A stimulus is said to control some aspect of behavior if a change in the behavior regularly follows a change in the stimulus. We "go" when we see a green light, and "stop" on red; we slap at the stab of a mosquito, which, in its turn, was attracted by the warmth of our body. Clearly, much of our activity and that of other animals is regulated by a never-ending flux of stimuli, yet stimuli cannot be taken for granted. To some physical changes our sense organs are insensitive (for example, radio frequency radiation). To many others, at a particular moment, we are potentially sensitive but actually indifferent, for we live in a sea of stimuli and can react to relatively few. Some stimuli come from external sources, some from within our bodies.

Stimuli have other functions that are not specifically tied to the current direction of activity; for example, they may act as reinforcers or punishers. They may cause satiation or bring about a variety of physiological changes. These important stimulus functions are discussed elsewhere in this volume and so are not the principal focus of this chapter.

Our concern here will be mainly with learned control, with the correlations between stimuli and responses that arise from past experience. Although the bulk of research on discriminative control concerns such learned behavior, it is well to recognize the variety of sources from which control may spring. Let us consider for a moment some functional aspects of this problem, in order to provide a background for our concentration upon the learning research.

Sources of Discriminative Control

To survive as individuals—and as species—animals must do the right thing at the right time, just as they must have appropriate bodily structures. According to the "survival of the fittest," the animal with the fittest behavior survives. Thus, behavior has evolved, just as has structure, and the result is a variety of behavioral mechanisms, each appropriate to its function for the organism.

Some stimuli have constant consequences for a species from year to year and generation to generation. If simple reactions to these stimuli suffice, an organism may be equipped to deal with them without benefit of experience. However, as behavior grows more complex, and the environment more demanding, it becomes efficient, even necessary, for the animal to acquire some of its behavioral equipment through experience. If survival depends on adaptation to changing circumstances, so that a response to a stimulus that was effective at one time becomes useless or harmful at another, it becomes vital for the organism to learn. In most higher animals it is clear that the genetic information that controls behavior is supplemented by information arising from the individual's contact with its environment.

It is equally clear that the genetic and environmental are not strict alternatives, as the old "nature-nurture" controversy might suggest. In any given case there seems usually to be a very complex interplay between the two. Nonetheless, it is useful to think of discriminative control as a kind of continuum. At one end fall genetically controlled, stereotyped responses to simple stimuli; at the other fall complex modifiable responses to complex, changing stimuli. At one end, we find the simplest unconditional reflexes—an eyeblink to a puff of air, salivation to food in the mouth. Even these are complex and labile in higher organisms, when compared to some responses in insects and simple organisms. The adaptive possibilities of even simple reflexes are expanded enormously by the possibility of habituation and, at least in higher forms, of Pavlovian conditioning. These may alter the incidence of a response or put a response under the control of an indefinite number of stimuli; the sight of food elicits salivation, a signal paired with shock elicits various emotional responses, and so on.

Orientation

A type of discriminative control that has long fascinated researchers involves responses to "guiding" environmental stimuli. The moth's attraction to light, the behavior of homing or migrating birds, the swimming patterns of spawning salmon, and the tendency of human infants to maintain eye-to-eye contact with the mother while nursing are examples of such "locked-in" or guided behavior probably under the control, at least initially, of genetically programmed stimuli.

Such behavior has been classified into categories bearing descriptive names, only a few of which we can mention here. In *kinesis,* the stimulus does not point the organism in any particular direction but simply stimulates it to move or turn. Certain insects, for example, congregate in damp places, presumably because dryness generates activity that diminishes or stops when, in moving here and there, the insect comes upon damper conditions. In *taxes,* the position of the body is determined by the source of stimulation. For example, an animal may sample light stimuli arriving at its two sides, either successively, by swinging its head, or simultaneously, if it has lateral eyes. Often the result is a movement that equalizes the stimulation coming

from the two sides. The animal would approach a light, for example, if as it moved it turned continually toward the side of its body receiving the most light.

Modern workers have suggested the similarity between the behavior described above and man-made control systems, in which deviations of input from a prescribed balance produce "feedback" adjustments that change the input until the balance is reached. This is the principle behind an aircraft's automatic pilot. Even the malfunctions of such systems have their counterparts in the mechanism of orientation in living things. Thus an organism that turns toward the light may whirl endlessly if one eye is blinded or covered.

Complex problems of animal orientation, such as the interesting work of von Frisch on food-finding in bees, or the still little-understood mechanisms underlying the feats, undoubtedly in part learned, of homing or migrating birds, cannot be considered here in detail. (For more extensive discussion of such behavior, see Fraenkel and Gunn [1940], von Frisch [1950], and Hinde [1970].)

Fixed Action Patterns

At another point on our adaptive continuum are certain stereotyped behavior patterns, often quite complex, that have usually been observed and analysed in relatively natural settings. A defining characteristic of these *fixed action patterns* is that once they have been set in motion, they keep going independently of the initiating stimuli, which are said to "release" them. An oft-cited example is the egg-rolling response of the greylag goose, which serves to get misplaced eggs back into the goose's nest (Figure 17.1). The goose, in a manner similar to that of many other ground-nesting birds, stands up and, stretching its head forward, rolls the egg back with the underside of its bill. The presence of the egg in this case releases the retrieving motion, but the stereotyped nature of the response is evident, for if the egg is removed during retrieval, the goose continues to "roll" the now vanished egg until the pattern of motion is complete.

Figure 17.1. Greylag goose retrieving an egg, an example of a "fixed action pattern." If the egg is removed while it is being rolled back, the head continues its stereotyped movement toward the nest. (After Tinbergen, 1951.)

Many such fixed action patterns have been studied, and specific stimuli that trigger them have been identified. The manner in which the effective stimuli are found is essentially the same as that which, as we shall see, is used to identify stimuli in complex learned tasks. One varies the situation in this way and that, and notes which variations leave the response unchanged. For example, Tinbergen (1952) used fish models to determine which stimuli released fighting and courting behavior in the male stickleback, a small fish. When sexually active, the male stickleback often attacks intruding males, but attacks females less often and may court them. Sexually active males have bright red bellies. Males attacked even very crude models that were painted red on the bottom but reacted much less to good likenesses of the fish lacking the red bottom. Similarly, crude models with swollen bellies elicited more courtship behavior than did more realistic but slim models.

Imprinting

Though cues eliciting responses of the kind just discussed are not learned in the sense that neutral stimuli are transformed into effective ones through reinforcement or other experience, it is not correct to conclude that experience is irrelevant to this sort of discriminative control. Our discussion of this

matter follows, to a large extent, that of Hinde (1966), where further details may be found. It is most significant that naive animals—newborn, or isolated from stimuli in one way or another—often emit characteristic patterns of response to a very wide range of stimuli. Certain baby birds, when they first open their eyes, will "beg" to a wide range of stimuli (for example, a pair of forceps); very young kittens will suckle from any receptive mother; newly hatched chicks will peck at any small dark or bright spot. In these and similar cases, the range of stimuli that elicit the response becomes drastically narrowed with time. Thus, in the normal course of events, the bird will beg only from the mother (or other object to which it is accustomed); the kitten will suckle only from its own mother; the chick will peck only at food grains or similar stimuli. Hinde attributes much of this narrowing of effective cues to habituation (that is, a diminution in the number of responses made to frequently presented stimuli that lead to no consequence) and to reinforcement. For example, chicks continue to peck at stimuli that release the actions of grasping and swallowing, and stop pecking at those that do not.

The most studied case of such a narrowing of the range of effective stimulation concerns the stimuli that elicit following behavior in birds that leave the nest soon after hatching. A gosling or duckling will follow almost any moving object it first sees—its mother, a slowly walking man, an inflated balloon, and so on. Shortly, new objects will not elicit following; the bird will only follow the objects it has already experienced, or similar ones. This phenomenon is called "imprinting." Controversy still surrounds the nature of the acquisition process here (Sluckin, 1965). Some writers feel that it is a special case of ordinary conditioning, others that it is different enough to be considered as a quite distinct process. A most interesting property of imprinting, in any case, is that it can only occur within a relatively short "sensitive period." Chicks, for example, come to follow an object to which they are exposed from the age of a few hours to a few days, but if their experience comes earlier, or is put off later than this, they will not even learn to follow the mother hen. (See also the discussion of imprinting, pp. 581-588.)

Various forms of discriminative control may be intertwined at every behavioral level. Two examples serve to illustrate this point. Lorenz (1937) found that greylag geese easily became imprinted upon him if they saw him moving near them right after they hatched. The goslings followed him consistently as he walked and swam, yet one specific unlearned releasing stimulus—the wing-pattern of the goose upon taking flight—would supersede the "learned" response to Lorenz and elicit following behavior. Likewise, Breland and Breland (1961) discovered with some surprise and disappointment that species-specific control intruded into the acts of performing animals that they tried to train. For example, pigs trained to deposit large wooden coins in a "piggy bank" developed the habit of rooting and tossing the coins about—behaviors controlled by food stimuli in the ordinary life of a pig.

Discrimination Learning

From an adaptive point of view, it is the consequences of behavior, rather than particular actions themselves, that are important to the animal. Food must reach the stomach of the parent, and also the stomachs of the helpless young. Predators must be avoided, eggs fertilized, and so on. These consequences remain relatively simple, as compared with the complexity and variety of the behaviors that can lead to the consequences. It is not surprising, therefore, that mechanisms have evolved that will lead animals to appropriate consequences, without passing on genetically a relatively large burden of information about the necessary specific actions involved. This is the evolutionary rationale for the principle of "reinforcement," which we have met before (Chapters 15-16). Most of this chapter is concerned with modifications in stimulus control under the influence of reinforcement.

Reinforcement and punishment are ap-

plied systematically in experiments to yield discriminative control. The responses controlled may be of any instrumental type, such as running toward, jumping at, or pushing on a stimulus source. The response locus can actually be some distance removed from the cue source or sources. The stimuli for discrimination learning may involve any of the sense modalities or even, as in position discrimination, kinesthetic feedback from the organism's own activity.

This chapter is concerned with both discrete-responding and free-operant (or multiple-responding) learning situations. Differential conditioning (also a form of discrimination learning, perhaps the most rudimentary) has been mentioned elsewhere. In discrete-trial situations, the experimenter controls the stimulus presentations, and the trial ends when a response has been made. The subject is either reinforced or not, depending upon the "correctness" of the behavior and the reinforcement schedule employed. Under discrete-trial procedures, the subject is usually permitted either one response or a predetermined amount of time during which a response may be made. In the free-operant situation (Ferster, 1953) the organism can continue responding in the presence of the discriminative stimuli until a correct response has been made, or until a certain time has passed, or until an arbitrary number of responses has occurred.

Historically, studies of performance in discrimination learning situations often were carried out to assess the sensory and behavioral capacities of various animal species. Animals can be trained to respond differentially to quite different stimuli, and then tested with stimuli that are progressively more similar, until a limit is reached at which no difference can be detected. For example, an animal might be fed for approaching the brighter but not for approaching the dimmer of two lights. One could then determine the smallest brightness difference between two stimuli that still permits the animal to respond differentially.

The techniques described above were originally designed by comparative psychologists to find out what animals hear, see, taste, and smell. However, it became increasingly apparent that discrimination learning depends upon experimental variables the effects of which should be studied in their own right. For example, why are some discriminations learned faster than others? To find out, stimuli and reinforcement conditions may be varied, and the course of acquisition may be followed by plotting some response measure over practice trials. Usually, response strength is expressed as the proportion of responses or the number of trials that are correct. Learning trends may also be assessed in terms of the relative latencies of response to different stimuli, a procedure that is particularly appropriate when there are no "incorrect" responses but, instead, alternatives that yield different reinforcing consequences (Logan, 1952).

It should be apparent that discrimination, or differential responsivity, is the obverse of generalization. When an organism responds in the same way, or similarly, to two or more stimuli it may be said that generalization exists among the stimuli—for *that* organism executing *that* response. Discrimination involves the absence or diminution of generalization and, in discrimination learning, the progressive increase in the probability of making different responses to different stimuli. Between total generalization and perfect discrimination lies a continuum of differential responding, manipulable through reinforcement contingencies. The study of this differential responding, and the variables that affect it, comprises the study of discrimination learning.

Because an organism's discrimination is always assessed through the measurement of some particular response property, discrimination performance can be at the same time both excellent and poor, even with respect to the same set of stimuli. Thus, a subject might choose an incorrect stimulus as often as a correct stimulus, but take longer to choose the incorrect one. "Percent correct" would show no discrimination, but "latency"

would. Thus the discriminative capacity of the subject must always be defined in terms of the response measures that are used. Realization of this point helps to avoid the empty questions that sometimes arise as to whether an organism *really* can tell the difference between two stimuli even though it is not currently responding differentially. To say that a rat can tell the difference between a black card and white card means that under some circumstances a differential response will be made.

PROCEDURES

Many methods have been devised since the start of systematic work on discrimination learning about 1900. To some extent, the variety of the methods reflects the variety of the subjects studied, for one cannot present the same stimuli to, nor record the same responses from, a child, a mouse, a worm, a chimpanzee, and an octopus, although all of these, and many other organisms, have been used in discrimination experiments. The great bulk of the work, however, has been done on just a few species, the white rat mostly, but children, monkeys, and pigeons are currently popular subjects also. Methods also vary widely with the purposes of the experimenter, who may proceed quite differently if he is interested in, say, visual acuity of an animal subject than if he is interested in the effects of food deprivation upon learning speed. His apparatus and procedure may also include aspects dictated by his particular theoretical orientation.

Despite the diversity of prevalent methods for the study of discrimination, they all involve certain common problems as well as common principles. Also, the evolution of method has shown consistent trends through time. These trends are in the direction of gaining increasingly precise control of variables (making it possible, for example, to state exactly what stimulus is reaching the subject), eliminating extraneous variables (for example, by isolating the subject), improving efficiency (producing, for example, faster learning, thus allowing more trials per day), and greater simplicity. This last trend is particularly important; it contributes to all the others, and in addition the outcome of a simple experiment (few stimuli, few response possibilities) is usually easier to interpret than the experiment with many complex possibilities.

Figure 17.2. Partial floor plan of the Yerkes discrimination box. The small squares represent the positive and negative cues on the wall, and the broken lines are the alternative routes. The route that passes the positive cue leads to food.

Discrete Trial Methods

An early apparatus used to teach animals to discriminate between stimuli was designed by Yerkes (1907; Yerkes & Watson, 1911) for the study of visual sensory capacities in mice and rats. A partial floor plan of this so-called "discrimination box" is shown in Figure 17.2. The little squares on the wall at the far end from the starting position represent the positive and negative cues. The animal chooses a cue by walking past it into the outer alley. If it chooses correctly, it finds food at the end of the outer alley; if not, it gets nothing. As can be seen, this apparatus permits correction: If the animal first responds to the nega-

tive stimulus, it may go to the other side and receive the reinforcer. Note several things about this method: the subject cannot see one stimulus while responding to the other; it walks near the stimulus, rather than actually touching or responding "to" it; reinforcement is delayed because the animal must go on to the end of the outer alley to get food; there is no punishment for incorrect responses.

The early experimenters often took greater pains to control stimulus variables such as light intensity than they did to facilitate the animal's learning, and all of the factors just listed are now thought to make for slow and variable learning. Later workers sought methods that would yield faster training, less response variability, and a closer approach to

Figure 17.3. The Lashley jumping stand. If the rat jumps against the correct door, it opens and the rat finds food. If the rat jumps against the wrong door, which is locked, it falls into the net.

the subject's discriminative limits. When Lashley (1930), for instance, began an extensive study of pattern vision in the rat, he abandoned older methods because of the enormous number of trials it took an animal to learn to discriminate, for example, between a circle and a square. He devised a "jumping stand" that yielded much quicker learning (Figure 17.3). Improved forms of the Lashley jumping stand have since been reported (Lashley, 1938; Tolman, 1939; Finger, 1941; Ehrenfreund, 1948; Feldman, 1948; Maier, 1949).

Suppose one wanted to teach a rat a black-white discrimination in the Lashley jumping stand, with black as the negative stimulus and white as the positive. In preliminary training, the stand is placed close to an open door, with food behind, and the rat walks in. The stand is moved progressively backward on successive trials until the rat must jump the gap, which may be increased eventually to 10 inches or more. Next the rat is offered an easy choice between a closed black door and an open door with food beyond; then a few trials later a white door is substituted for the open one. Finally, the black door is locked, and if the rat jumps incorrectly it bumps into the door and falls into a net below. If it jumps against the correct door, in contrast, it pushes it open and finds food on the platform behind. When the black and white doors are shifted from side to side in random order, response to the positive stimulus is often established in as few as 4 or 5 trials (see p. 601).

The speed of learning that is achieved with the Lashley jumping stand is probably aided by the fact that the rat can see both stimuli at the time of choice, that it jumps directly at the chosen stimulus, and that it gets food immediately for correct jumps. Also, it is punished by the bump and fall for incorrect responses.

Punishment tends to facilitate learning in many situations, but it can also cause trouble. For example, sometimes rats will not jump, even after a careful, gradual approach to the
final conditions. This happens particularly when the stimuli to be discriminated are quite similar or when the discrimination problem is insoluble (for example, both stimuli are correct on a random half of the jumps). Investigators faced with rats that would not jump (Feldman, 1948; Maier, 1949; Maier & Ellen, 1951) have resorted to shocking the animal, or blowing air on it, if its response latency on a trial exceeded an arbitrary limit. Such procedures keep the rat from sitting the whole trial out, but in all likelihood they affect the animal's discrimination performance as well. Animals treated in this way, for example, typically develop perseverative or "fixated" responses (see p. 791).

Other variations of the Yerkes box for small animals have been made that retain its maze-like character in simplified form. In the T-maze and the Y-maze, for example, the animal proceeds from a start box through a single alley to a critical juncture. Here, with both positive and negative stimuli in view, the animal turns either left or right. Correct choices lead to reinforcement at the end of the chosen arm; incorrect choices yield no reinforcement or, in some experiments, punishment by shock.

Variations on the classic techniques just described have been devised to suit many subject species. Subjects that can manipulate objects readily, such as monkeys and humans, have usually been required to grasp or touch choice stimuli rather than to run or jump to different places. Hobhouse (1901) found that monkeys will learn quickly to pull in a food container placed beyond reach but attached to an accessible string. If there are two such containers, one smaller than the other but which always contains the food, the monkey learns to pull in the smaller. Monkeys can learn to rely on brightness and shape as well when they make a choice (Klüver, 1931, 1933). Rats also may be taught, with patience and tact, to pull in food containers by aid of a string (McCulloch, 1934; McCulloch & Pratt, 1934), but this kind of response is not particularly easy for them, whereas it is easy for
Figure 17.4. The Wisconsin General Test Apparatus (WGTA). The monkey displaces one of the stimulus objects on the stimulus tray. If his choice is correct, the monkey finds a bit of food in a hole under the object. After each trial, the experimenter lowers the forward opaque screen, raises the one-way-vision screen, puts food in one of the holes, and resets the stimulus objects according to a prearranged plan. Then he moves the screens to start a new trial.

monkeys, which naturally use hand-over-hand responses in the wild as they forage for food in the trees or flee from enemies.

Perhaps the most widely used method for studying discrimination learning in primates employs the Wisconsin General Test Apparatus (see Figure 17.4). Harlow and his colleagues (Harlow & Bromer, 1938; Harlow, 1949; Schrier, 1961) devised the most recent versions of this apparatus. The evolution of the apparatus has been interestingly traced by Meyer, Treichler, and Meyer (1965), beginning with the use of the Yerkes-Watson box by Johnson (1914, 1916) adapted to cebus monkeys. Kohts (1923) studied matching in chimpanzees by requiring them to pick an object from a tray after seeing or touching a sample. Gellermann (1933a, b) devised a multipurpose piece of equipment for comparative studies

of chimpanzees and children. He mounted a pair of food boxes side by side on a shelf. Initially he had the stimulus patterns placed in an area between the boxes, but this procedure failed; when he placed the cues directly on the box lids the chimpanzees learned to work out the problems. Spence (1937) used an immediate predecessor of the WGTA that Meyer (1965, p. 6) calls the first apparatus ". . . to combine efficiency, convenience, and control of variables . . ." The discriminanda here were sheet-metal forms attached to boxes that the ape could tip up to expose food beneath. Among the reasons that Spence gave for the success of his apparatus were the facts that the relevant cues for learning were set apart distinctly from those that were irrelevant, and that the apes were required to push the stimulus forms directly, so their responses were temporally and spatially contiguous with the presentation of the reinforcement.

In the WGTA, food boxes have given way to food wells cut into a tray, and the stimulus figures cover these wells. The caged animal and the experimenter face one another across a table that supports the test tray. Two screens may be lowered between the subject and the experimenter. An opaque one keeps the subject from seeing the experimenter setting the stimuli on each trial, and a one-way-vision screen allows the experimenter to observe the animal during trials. Several adaptations of the basic WGTA have been developed for the study of visual discrimination learning in infants (Weisberg & Simmons, 1966) and older children (Spiker, 1956; Lipsitt, 1961), and in rats (Shepp & Eimas, 1964).

Automated Methods

One bothersome characteristic of the methods just described is that all require the constant attendance of an experimenter. Apparatus such as the maze or jumping stand also requires the experimenter to pick up the animal after each trial and put it back in the starting location. This is time-consuming and it introduces variability, which sometimes can be serious, for an inexperienced experimenter may squeeze a rat too hard, while even a trained experimenter has trouble treating each animal the same on all trials every day. To reduce these difficulties, more and more experiments are now controlled by automatic switching equipment and are run with animals completely isolated. Thus, instead of choosing between two doors or two alleys, a rat may be placed in a closed box to press one or two levers or push one or two plastic panels with its nose. The latter arrangement allows visual stimuli to be projected on the panels, so the subject responds directly to the stimuli—a procedure that, as we have seen, was helpful in the older methods. Trials in such experiments are separated by withdrawing the levers or by presenting some obvious inter-trial stimulus during which responses are not reinforced. If pigeons are used as subjects, darkness can often be used to separate trials because the birds are relatively inactive in the dark.

Automation saves time and reduces variability. In addition, more complex stimulus and reinforcement sequences may be scheduled than are possible with manual control, and each event occurs at just the right moment. If switches are attached to response levers or panels, responses may be made to drive counters, chart recorders, tape punches, or computer input systems. Long sessions can be run; sometimes, the animal may even stay in the experimental chamber continuously for days. Automation also means that the animal's behavior can be used to control subsequent events in the experiment. Thus, in discrimination experiments the presentation of the stimuli can be controlled by the subject himself. Such self-presentation of stimuli is often relied upon, for example, in the matching-to-sample experiment. In a typical case, a pigeon subject is confronted by three dark keys. A trial starts when a sample stimulus appears on the center key. This sample remains until the bird pecks at it, an "observing response" that assures the bird's exposure to the stimulus. By making this response, the

bird turns off the sample and exposes itself to the choice stimuli, one on each side key, between which it must then choose.

Free-operant Methods

Automatic apparatus is a feature of the methods pioneered by Skinner (1938). However, as is described in Chapter 14, these methods typically measure response rate, rather than recording a series of choices, as in a T-maze, a jumping stand, or a Wisconsin General Test Apparatus. Rate adds a new dimension to the standard variations of the discrete trial methods. Corresponding to the "go-no go" paradigm, where the animal is confronted on any trial with a stimulus to which it may or may not respond, the "multiple schedule" procedure presents a single key or lever to the subject; two or more states of a stimulus indicate periods during which the subject will receive reinforcement on some schedule for responses to this operandum. For example, a red light on the pigeon's key might set the occasion for reinforcement on a variable-interval schedule, while green indicates a period of extinction. In the operant literature, stimuli associated with specific reinforcement contingencies are often called "discriminative stimuli"; if a response is reinforced in the presence of a stimulus, that stimulus is called the "S+" or "S^D." If responses are never reinforced in the presence of a stimulus, the stimulus is called "S−" or "S^Δ." As we have seen in Chapter 14, many schedules of reinforcement may be programmed, with the result that S+ may indicate reinforcement available according to a variety of contingencies; there may be several S+s, each associated with a different schedule.

Corresponding most closely with the typical simultaneous choice procedure (see p. 774) is the so-called "concurrent schedule." Here, two (sometimes more) operanda are available simultaneously. The animal may operate either freely, and may switch from one to the other at will. An analogue of the "successive" procedure in this situation might be, for example, a bright light in the chamber setting the occasion for reinforcement (on some schedule) of pressing the lever on the right, whereas a dim light indicates reinforcement of pressing the lever on the left. More typical is the "simultaneous" variant. The bright light is always over one lever, the dim over the other. At a given time, the stimulus conditions may reverse, but both levers and both stimuli are always available.

In a given case, many considerations enter into the decision of whether or not to use a discrete-trial single-choice procedure or a free-operant discrimination with a rate measure. For a given stimulus presentation, rate provides more information about the tendency to respond than does a single response; given the simultaneous choice between two stimuli, a subject might always choose a particular one, yet we might find that the subject responds rapidly to its chosen stimulus under certain conditions but slowly under others. In following the course of discrimination learning, the rate of response in the presence of S+ may stay relatively constant, whereas the rate to S− declines; this may imply a process different from that which controls an increasing rate to S+ and a steady rate to S−. However, both of these changes might show up equally in a choice test as a rise in percent correct.

In contrast, the very freedom of the free-operant method often makes it hard to analyse the results of an experiment. For example, when two levers are present, the act of switching from one to the other sometimes appears to be a response quite different from repeated responses to the same lever (Catania, 1966). A further objection to relying on the free-operant method in discrimination studies is the fact that reinforcement itself may enter the experiment as a discriminative stimulus. In a discrete-trial experiment, reinforcement only comes at the end of a trial, and it provides no information about how to respond during that trial. In a multiple schedule, if the S+ remains on after the subject has received one of his scheduled reinforce-

ments, it will not be clear whether subsequent responses are controlled by the S+ or whether they occur, at least in part, because the reinforcement itself has provided a cue that further reinforcement is possible (Blough, 1966; Jenkins, 1968b). Thus, experimenters who have chosen the free-operant method for discriminative work often change stimulus conditions randomly after reinforcement, or examine only data from stimulus presentations that omit reinforcement altogether.

One common application of the free operant method has been to the testing of stimulus generalization, using the technique pioneered by Guttman and Kalish (1956). In this technique, the subject receives prolonged training with intermittent reinforcement in the presence of one stimulus; then reinforcement is omitted entirely, and the stimulus is varied at brief intervals. The rate of response to each test stimulus contributes to a generalization gradient that is not biased by the occurrence of reinforcement, for the test is run in extinction.

Complex variations of operant methods have been applied to specific problems in animal psychophysics, and it is very difficult to describe them briefly in general terms. We shall return to the problems briefly below (see Blough, 1966).

COMPARATIVE PSYCHOPHYSICS

The desire to find out about the sensory capacities of animals has long been an important reason for doing discrimination experiments with animals. This has come about because physiological and anatomical information about animal sensory systems is being collected with increasing rapidity and, with behavioral data from the same subjects, it is possible to put together a much more complete picture of sensory functioning than can be done with physiological data alone. Working with animals also affords the opportunity to carry out sensory research with important but possibly dangerous variables—studies, for example, of the effect of very intense noise on hearing.

It is in the behavioral study of animal sensory functioning, which could be called "comparative psychophysics," that we see most clearly the overlap between the methods of human psychophysics (Chapters 2 and 3) and those discussed in this chapter. In both kinds of work the experimenter may ask what the subject sees, hears, smells, and so on. Thus psychophysics is set apart from other work on discriminative control by its emphasis on well-learned discriminations rather than upon the learning process itself. It is also set apart by its emphasis upon the effects of simple stimulus changes, rather than complex stimuli or motivational and incentive variables such as level of deprivation or the nature of the reinforcer. In psychophysics, the aim is to find out how dim a light may yet be detected, how similar are two tastes, how loud is a tone, and so on.

Methods

Chapters 2 and 3 discuss in detail the methods employed in human psychophysics. The animal case differs primarily in the way that the subject is instructed and kept responding. The human subject is told what to look for and what to do. The animal must be reinforced for looking and for doing and perhaps punished for inappropriate behavior. These reinforcement conditions must be woven into the psychophysical procedure in such a manner that they generate the desired behavior but do not provide interfering cues. The apparatus and procedure used depend, of course, on the subject species, the sense modality, and the particular problem of interest. Certain common problems are faced in all sorts of research, however, and we can illustrate some of them by describing a single experiment.

Let us ask if pigeons can detect odors. Like other birds they apparently have the necessary physiological apparatus, but there is little evidence that the smell of things affects their behavior. Michelsen (1959) carried out an
Figure 17.5. Apparatus for pigeons in Michelsen's olfactory experiment. Pecking the observing key started air flowing through the cylinder on the left. Nine seconds later, another peck on the observing key turned off the lights outside the cylinder and turned on a light inside. Then the bird pecked key *1* if an odor was present, key *2* if not. (After Michelsen, 1959.)

experiment to answer this question using a free-operant method. His pigeon subject was isolated in an experimental chamber with one wall built as shown in Figure 17.5. The bird had three keys to peck. Two of these (*1* and *2* in Figure 17.5) were choice keys; the left key indicated "odor present," the right "odor absent." Odorous stimuli were introduced on an airstream that flowed down a cylinder covering the choice keys. The bird placed its head in this cylinder through a hole (*A*) when a choice was to be made.

Let us develop Michelsen's procedure in answer to typical questions about an experiment of this kind. We start with the idea of forming a simple discrimination: reinforce pecks at the left key if an odorous substance is present, reinforce pecks to the right key if it is absent. What difficulties must the procedure take into account? First, extraneous stimuli must be excluded. The presence or absence of the odorous substance is just one thing that may be correlated with reinforcement. For example, there may be a click when the valve inducing an odorant is operated. The valve should be silent. The air should move at equal speed whether an odorant is there or not. To check such conditions, the odorant is sometimes omitted from the bottle upstream, to see if any discrimination may be maintained without it.

One important extraneous stimulus, unhappily often overlooked, is the occurrence of reinforcement itself. Suppose we decide to present odorous air for 3 minutes and pure air for 3 minutes, alternately, and to reinforce pecking at the left key on an intermittent schedule when the odor is present and at the right key when it is absent. Suppose the schedule of reinforcement is a fixed ratio of 10 (see p. 605). The pigeon can achieve an excellent score without smelling the odor at all, simply by pecking a few times at each key alternately. When reinforcement comes following pecks on the left key, the bird continues to peck on that key until reinforcements stop coming, then switches over and tries the right key.[1] Michelsen solved this problem by dividing his session into trials. A trial ended with reinforcement after 7 correct pecks were made, or without reinforcement if 4 incorrect pecks were made first.

Another difficulty that sometimes arises in two-choice experiments of the kind described above is the appearance of a habit that may mask discriminative control by the stimulus. Let us say that odorous air is present on half of the trials in the experiment, and pure air on the other half. By responding to one key only, on all trials, the pigeon could receive reinforcement on half of the trials. Many subjects are content with this situation; one cannot indicate to them that they would get more food if only they would pay attention

[1] Jenkins (1965a) discusses this general problem in the context of discrimination experiments.

to the stimuli and switch their responses accordingly. For this reason most experiments use a "correction" procedure, as did Michelsen in his odor experiment. If a trial ended with incorrect pecks, the stimulus conditions were repeated on the next trial. Thus, after an error, the pigeon could never get reinforcement, and get on with the experiment, until it switched keys away from the currently incorrect side. Such "correction" trials cannot be counted as part of the measure of the subject's discrimination, of course, because the lack of reinforcement on the previous trial can act as a cue controlling responses on the correction trial.

The correction procedure encourages the subject to abandon position as a cue and to attend to stimuli of interest to the experimenter. Another way to facilitate this attending behavior is to have the subject make some explicit "observing response." We have already seen that the Lashley jumping stand and the WGTA probably work well partly because they make the subject look at the discriminanda. In Michelsen's experiment, the odorous air did not fill the whole chamber, but flowed instead through the cylinder over the choice keys. A key outside this compartment (see Figure 17.5) was used for the observing response. A trial began when a house light was turned on in the outer chamber, with this third key lighted. When the bird pecked this observing key, air began to flow through the cylinder. Nine seconds later, when air bearing the odor had filled the small chamber, another peck on the observing key turned off the house light and turned on lights in the small chamber. This was a signal for the bird to put its head into the small chamber and choose between two keys (key *1* and key *2* in the figure), key *1* if an odor was present, key *2* if not.

Using the method just described, Michelsen found that pigeons did appear to discriminate odors. With two odorous substances the birds did better than 80 percent correct, while on control days, when the stimulus air passed through water without an odorant, performance fell to chance levels. We shall pursue this matter a bit further, since more information has since been gained by a technique that exemplifies a different approach to the problem.

This new method really involves both operant and classical conditioning (Chapter 14), for it uses the "conditioned suppression" (or "conditioned emotional response") effect (pp. 712–717). The main idea is to train an animal to emit a response, using some intermittent schedule of reinforcement such as a variable interval (p. 605). The stimulus that the animal is supposed to detect is then turned on at intervals, and after a brief presentation, which may be considered the CS, a shock (US) is delivered. If this is done, and if the proper values of stimulus and shock are maintained, classical conditioning of emotional responses usually occurs swiftly: the subject slows its responses or stops altogether in the presence of the conditioned stimulus.

Using an apparatus in many ways similar to that of Michelsen described above, and the suppression method, Henton, Smith, and Tucker (1966) studied odor detection in pigeons. However, only a single key was used, and the pigeon was reinforced on a 2-min variable-interval schedule (p. 605) for pecking at this key. This schedule generated a moderate rate of pecking. After this behavior became stable, the birds got 10 suppression trials in each 1-hour session. During these trials, air with an odorous substance added (amyl acetate) passed through the bird's chamber for 18 seconds; then the bird got a brief shock through electrodes implanted below its tail. The experimenters recorded key pecks during the olfactory stimulation, and also key pecks during the 30 sec period just prior to the odorous stimulation. They used the formula for the suppression ratio:

$$\frac{\text{prestimulus responses} - \text{stimulus responses}}{\text{prestimulus responses}}$$

to measure the detection of the odorous substance. If the substance had no effect, this
Figure 17.6. Apparatus used to track the pigeon's absolute threshold to light. Pecks on key *A* moved the wedge down (darker); pecks on key *B* moved it up (brighter). See text for details. (After Blough, 1958.)

ratio would be zero, whereas complete suppression would yield a ratio of 1.

The experimenters found that birds gave very few responses in the presence of 5 to 7 percent vapor saturation of amyl acetate. They ran a number of controls, making sure, for example, that changes in the flow of air during stimulation were not being used as a cue. They also showed that response suppression disappeared when the birds' olfactory nerves were cut.

Another method, called "tracking," is very useful for certain kinds of problems. This is again a two-response procedure, but it is distinguished by the fact that the responses not only indicate the subject's choices, but also serve to adjust the stimulus to some value of interest. For example, in a series of experiments, Blough (1958, 1961) reinforced pigeons for pecking one response key (key *A*) when a stimulus patch was visible and another (key *B*) when the patch was not (Figure 17.6). These pecks sent signals to relays that controlled the intensity of the patch. Pecks on key *A* reduced the intensity of the patch whereas pecks on key *B* increased it. Thus, if the bird could see the stimulus, it would peck on key *A*, causing the stimulus to dim and eventually to disappear. Then it would peck on key *B* to brighten the patch until it was visible once again; the cycle could then be repeated. In this fashion the bird kept the stimulus intensity oscillating up and down across its absolute threshold; a continuous record of intensity gave a graphic picture of the bird's threshold through time. Such a continuous record is especially valuable when we are interested in seeing how the threshold changes with time. For example, Blough used the method to study the course of dark adaptation and the course of drug action upon the threshold.

The tracking behavior is maintained by a rather complex set of reinforcement contingencies (for details, see Blough, 1958). Essentially, reinforcement is introduced into the situation at short intervals of random length by allowing responses to key *A* to turn off the stimulus entirely for a brief period. When the stimulus is off, key *B* pecks are reinforced by food, and tracking then resumes. Thus, to anthropomorphize, the pigeon works on key *A* to turn the light out, so that it can switch to key *B* and get food. The basic rationale of the method is that the bird cannot distinguish between the light dimming below threshold and its going out altogether.

Human and Animal Psychophysics: Signal Detectability

A maintained discrimination or a threshold experiment with animals has much in common with corresponding psychophysical experiments run with human subjects. As we have already seen, there are considerable differences in emphasis, for the experimenter using animals must spend much of his time training or "instructing" his subject, and maintaining its performance, whereas the emphasis in human methodology tends to be upon the ways in which stimuli are presented, the nature of responses, and the analysis of their interrelations (Chapters 2 and 3). These are, however, really differences in emphasis rather than in substance. The experimenter

working with non-human subjects has to decide upon a stimulus scheme (for example, he may choose the "method of limits," [page 14], or the "method of constant stimuli," [page 23]), and choose appropriate response categories. The human psychophysicist has to instruct his subject, and prepare to deal with motivational factors and response biases analogous to the reinforcement problems the researcher working with animals must face. The basic correspondence between human and animal psychophysics is no better shown than by reference to the theory of signal detectability (which was described with reference to human psychophysics, pp. 34–46).

Basic to the detectability approach is the notion of separating sensitivity from other variables that may affect a response in a discrimination situation. An experimenter can change the criterion of a human subject by such instructions as "Don't say 'yes' unless you are absolutely certain you detect the stimulus." Rewards and punishments may also change the criterion. Here, the experimenter using animals has a freer hand. In a simple case, a rat, for example, may be trained to detect a weak sound. If, during a trial indicated by a light in the rat's box, the sound is presented, the rat presses lever *A* for reinforcement, and is perhaps punished for pressing lever *B*. If no sound is presented, the rat can press lever *B* for reinforcement, and if it presses lever *A*, it is punished. The rat's sensitivity (as indicated by the quantity, d') is computed just as is a human subject's (p. 41) from the proportion of "hits" (*A* presses, given a sound) and "false alarms" (*A* presses, given no sound) that it makes.

The procedure described above has two advantages. If we are interested in the rat's sensitivity (we might be studying mechanisms in the ear, for example), d' gives an estimate that is unbiased by the kinds of lever preferences and motivation changes that plague work with animals. If we are interested in the discriminative mechanisms including motivation and bias, we may change the animal's "payoff matrix" (p. 37) by varying the amount or relative frequency of rewards and punishments for pressing the two levers, while holding constant the influence of signal and sensitivity (see Hack, 1963; Boneau, 1967). Stebbins (1966) obtained additional information by recording the latency of response to an auditory stimulus. His monkeys held down a key until they heard a tone, which varied in intensity from trial to trial and in frequency from session to session. Tones that yielded equal latency were assumed to be equally loud, and Stebbins was able to construct "equal loudness contours" similar to those obtained from human subjects.

THE EFFECTIVE CUES IN DISCRIMINATED BEHAVIOR

What cues actually control the rat's choice between two doors of a jumping stand, a child's decision to press one of two stimulus panels, or, generally, any discriminated response? This is a familiar problem in many areas of psychology. In perception, for example, we may ask what aspects of the environment determine that we shall see objects "in depth" or "at a distance" or enable us to locate sounds at a particular source. These are not easy questions to answer, even in simple learning situations, yet upon the answers depend not only the understanding of any specific situation, but the understanding of discriminative processes generally. In this section we look mainly at the methods that have been devised to find the effective cues; we also look at some of the more important empirical results. In the next section we deal with some of the theoretical issues and debates that have surrounded experiments on discriminative control.

Several basic methods have been used to investigate the nature of effective stimuli. In one group of techniques, stimulus equivalence is directly tested. This group includes studies of "stimulus generalization," and "transposition." These studies start by generating a high degree of stimulus control and

then varying aspects of the stimulus situation to see which makes a difference in the response. By definition, "effective cues" are those aspects that, when varied, cause the response to vary.

Other methods do not start with a well-learned discrimination, but instead they measure primarily the subject's performance as he learns some new task. Here the notion is that stimuli that are effective in a given situation may help or hinder new learning; the kinds of tasks that are helped or hindered give us clues about the nature of the stimuli. Among these methods are studies of "reversal learning" and "learning set," for example.

A third group of techniques makes it possible for us to look at the behavior of the subject for indications of selection or attention, while he learns to discriminate between stimuli. Aspects of the learning situation may be changed to make the subject's stimulus selection processes more evident. Studies of "vicarious trial and error," "observing behavior," and "attention" are of this type.

Of course, the distinctions between the methods described above are somewhat arbitrary. Furthermore, many experiments involve the combination of several of these techniques.

Stimulus Generalization

Perhaps the simplest way of determining effective cues is found in the study of stimulus generalization, for here the stimuli are usually drawn from some well-defined physical continuum, and their effectiveness is inferred from a simple measure of response strength, such as rate, force, or latency. Studies of generalization show that the environmental conditions that control behavior are never unique events; one can always find a class of somewhat different events that also will set the occasion for the same response. Such stimulus generalization is necessary for survival, for situations never recur exactly; we must avoid collision with looming objects that come at us from various angles, respond to the same words pronounced with various tonalities and accents, and so on. The generalization phenomenon appears to be similar for both the conditioned stimuli whose control is established through classical conditioning, and the discriminative stimuli whose control is established through operant training procedures. To study stimulus generalization, experimenters usually train a subject to respond in a given way in the presence of a specific stimulus, and then observe how the response changes as that simulus is varied.

An early example of the study of stimulus generalization following classical conditioning is an experiment by Hovland (1937a, b) with human subjects. The conditioned stimulus was a tone, and the unconditioned response was the galvanic skin response (GSR) (p. 558) measured in terms of the amount of deflection of a galvanometer. Shock was paired with a tone of 1967 Hz until a good conditioned reflex had been established. Then the subject was presented with other tones (1,000, 468, and 153 Hz) spaced by successive steps of 25 jnds (just noticeable differences, p. 19) from the original conditioned stimulus. The height of the generalized GSR could thus be stated as a function of psychologically meaningful steps along the pitch continuum. The resulting gradient can be seen in the mean GSR (measured as galvanometer deflections) obtained from 20 subjects:

18.3 mm when the original tone was sounded
14.9 mm when the tone 25 jnd away was sounded
13.6 mm when the tone 50 jnd away was sounded
12.9 mm when the tone 75′jnd away was sounded

The gradient is far from steep in view of the wide range of pitch tested.

The experiment described above was actually more complex than it might seem from the description. All four tones were equated for loudness, to avoid any possible influence from this variable. Further, Hovland trained half his subjects on the lowest pitch rather

than the highest, and averaged his results in terms of "steps-removed-from-CS," just in case the higher (or lower) tone happened to be the more effective stimulus. (Such measures to isolate the effective stimulus variable are often an important part of generalization experiments.)

Hovland's experiment has the disadvantage that it was necessary to average the data of several subjects in order to show regular generalization gradients. In contrast, techniques more recently developed for use with animals routinely produce gradients from single subjects. An example of this, concerned with respondent generalization, is an experiment of Hoffman (1965), who used the conditioned suppression method that we have met before in this chapter and elsewhere (p. 712). The measure of the strength of the response is indirect; it is the degree of suppression of an on-going operant by a tone (CS) that has been paired with shock. Pigeons were first starved to 80 percent of their original weight and adapted to the apparatus, which is shown in Figure 17.7. They were then trained to key peck and placed on a 2 minute variable-interval schedule of intermittent reinforcement. Still without resorting to shock, Hoffman adapted the pigeons to the CS, a tone of 1000 Hz, and the test stimuli, tones of 300, 450, 670, 1000, 1500, 2250, and 4500 Hz. Finally, the CS tone of 1000 Hz was presented on an average of once every 10 minutes, lasting 48 seconds each time. During the last 8 seconds of each CS, shock UCS was presented. Approximately 600 trials over 70 sessions were required to reach a stable suppression of response to the 1000 Hz tone. Suppression was measured by the ratio

$$\frac{\text{pre-tone } Rs - \text{tone } Rs}{\text{pre-tone } Rs}$$

Note that if the bird pecks just as fast during the tone as before, this ratio equals zero, indicating no suppression; if it stops pecking entirely, the ratio is 1, indicating complete suppression.

During generalization testing, the bird was placed in the experimental box with shock
Figure 17.7. A view of the pigeon in the experiment on generalization of conditioned suppression. Shock was delivered through bead chain wrapped around the base of each wing. The pigeon pecked for food, but this pecking was suppressed when the loudspeaker sounded tones that had been paired with shock. (After Hoffman, 1965.)
Figure 17.8. Generalization gradients from one bird in the experiment shown in Fig. 7. Prior to these tests, the 1000 Hz tone had been paired with shock. The curves show that in the first few sessions the bird stopped pecking almost entirely whenever any tone came on. By sessions 21–25, its behavior was still suppressed to the 1000 Hz tone, but most of the other tones produced little effect. No shocks occurred during these testing sessions. (After Hoffman, 1965.)

connectors in place, but no shock was ever delivered. Each day, in an hour and a half, the 7 tones (including the CS, 1000 Hz) listed above were presented one every 10 minutes, for 40 seconds each. The sequence of tones was varied from day to day. Figure 17.8 shows the gradients of suppression obtained from one pigeon on successive blocks of 5 sessions. Note that at first the bird stopped pecking almost entirely when it heard any tone, although the 1000 Hz CS caused slightly greater suppression than the others. Gradually, the gradient became steeper and steeper, until only the CS produced substantial suppression. (Remember that no shock accompanied any tone during the testing sessions.) Other experimenters, working in both operant and classical conditioning situations, have also noted a sharpening of the gradient during the course of the testing interval.

Other findings of Hoffman were that increased deprivation narrowed his suppression gradients, and that when testing was resumed after a $2\frac{1}{2}$ year interruption the tones continued to cause suppression in the manner that one might have expected had testing continued without interruption.

The exact shape of the generalization gradient became an issue of considerable interest to some behavior theorists (Spence, 1937; Hull, 1943). However, it is now considered of questionable value to talk of any one particular gradient shape, even in a single experimental setting. The gradients change during testing and vary with things such as deprivation, as the Hoffman experiment illustrates. Also, the measures of response strength (the ordinate of the gradient graph) and of the stimulus dimension (the abscissa) both affect the shape of the curve (Blough, 1965). For example, a different way of measuring suppression (there are several different ratios in use) would change the shape of Hoffman's gradient even if identical data were fed into the suppression formula (see p. 713).

For such reasons as the ones mentioned above, emphasis has shifted from determining "the" shape of "the" generalization gradient, to attempts to specify the variables that may affect generalization and to interrelate results from differing kinds of experiments. Most of this research has been done using the rate of an operant response as the measure to which stimulus variation is tied. Many experiments have used pigeons as subjects and, as stimuli, different wavelengths of light, projected upon the bird's response key (Guttman & Kalish, 1956). A typical experiment is begun by training the pigeon to peck its translucent response key illuminated from behind by a single narrow wavelength band of light. Often, 550 nanometers (nm) has been used as the training stimulus in these studies. (This stimulus appears yellow-green to human eyes.) For perhaps 10 hour-long sessions the bird is reinforced intermittently on a variable-interval 1-minute schedule. Then, in a testing session, reinforcement is discontinued, and a set of differing wavelengths is given, each for perhaps ten 1-minute presentations mingled in random sequence with the others. The pigeon generally keeps pecking during most of this period, even though no reinforcement is given. Before it quits, it will
Figure 17.9. A typical generalization gradient from a single pigeon trained to peck a key illuminated by a light at 550 nm. Reinforcement ceased during the test, and lights of different wavelength appeared on the key. The bird pecked most at the wavelength formerly associated with reinforcement, and less at wavelengths differing from this.

have had several opportunities to peck at each of the test wavelengths. To some it responds rapidly, to others not at all. Counters record the total number of pecks emitted to each test stimulus; the gradient drawn from the experiment is made from the totals on these counters, as is illustrated in Figure 17.9.

You should not be led astray by the apparent asymmetry of the gradient in Figure 17.9, for this only illustrates our remarks about the importance of appropriate scales for gradients. Here the scale on the abscissa is a physical measure—wavelength. There is no reason to expect this psychologically arbitrary scale to yield a gradient of any particular shape. Recall that Hovland used for his scale jnds along the stimulus continuum: We might expect that these would have something to do with the degree of generalization between the various test wavelengths. Unfortunately, few data are available on pigeon jnds for hue, but what there is available does not seem to be related to the shape of generalization functions (Guttman & Kalish, 1956). Perhaps it is best to consider the gradient as defining the similarity of the various wavelengths to the training stimulus, as far as the pigeon is concerned. If a test wavelength yields about the same rate of response as the training stimulus, we can say that (by definition) the two wavelengths look similar to the bird; two wavelengths that yield differing response rates look different. Making use of this kind of analysis, it is possible to scale the wavelength continuum for similarity (Shepard, 1965).

Using various measures of response (rate, amplitude, and latency in particular), experimenters have explored stimulus generalization on a number of dimensions (Mednick & Freedman, 1960). Among these are the spatial dimension (that is, the distance between stimuli applied to the skin), frequency of tones, intensity and wavelength of lights, size, and temporal duration of various stimuli. In the last case, the training stimulus might be a tone of a particular duration, the test stimuli tones that are made to last for longer or shorter periods of time. In all of these cases, more or less regular gradients have been obtained, with response strength falling with decreasing similarity between the test stimulus and the training stimulus. With one or more of these dimensions, several variables have been found to affect the width of the gradient. For example, increased drive generally broadens the gradient, and so (within limits) does the number of training trials and the lapse of time between training and testing.

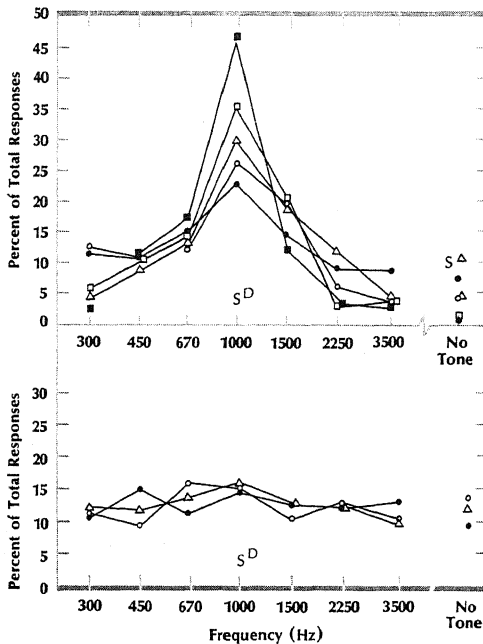
The conditions for a generalization decrement We have said before, somewhat loosely, that a stimulus is said to control some behavior if a change in the stimulus brings about a change in the behavior. For example, we would not include as "stimuli" those environmental changes, like radio waves, that never control behavior. Furthermore, many events that are potential stimuli never gain such control, because this potentiality is not realized without learning or other experience of some kind. It might seem from the examples of generalization experiments given above that all that is required to make a class of events into a stimulus is to reinforce some response in the presence of members of that class. We shock the subject in the presence of a particular tone, feed the pigeon in the presence of a particular wavelength, and so on. However the situation is not so simple, as is illustrated by an experiment of Jenkins and Harrison (1960). They trained pigeon subjects with intermittent reinforcement on the usual key-pecking task while a single tone (1000 Hz) was presented continuously in the experimental boxes. Following this training, a test sequence of different tone frequencies was presented. However, in this test, the birds responded as much to one frequency as to another. They "generalized perfectly," "failed to discriminate," or "failed to attend" to the frequency changes. Or perhaps we might say that this procedure failed to make tone frequency a stimulus for these birds. Simply exposing a subject to some physical energy


Figure 17.10. Each curve is a generalization gradient from one pigeon. Both groups were reinforced for pecking in the presence of the 1000 Hz tone. For birds shown in the lower graph, this tone was continuously present during training. Birds shown in the upper graph learned a discrimination with the 1000 Hz tone as S+, and no tone as S−. (After Jenkins & Harrison, 1960.)

may be inadequate to make changes in that energy become stimuli.

In contrast we saw above that sometimes simple exposure does seem to yield stimulus control. Do we have to be content to say simply that sometimes it does and sometimes it does not? Fortunately, we are in a somewhat better position than that. In the study mentioned above, Jenkins and Harrison (1960) also gave a group of birds discrimination training, sometimes presenting the 1000 Hz tone with reinforcement and sometimes turning off the tone and withholding reinforcement. When this was done, a gradient much like that found on the wavelength continuum resulted. Figure 17.10 compares the gradients with and without this differential training. Comparable results have been found by experimenters using other sorts of stimuli and punishment rather than reinforcement (Newman and Baron, 1965; Honig, 1966). So, as it turns out, differential reinforcement with respect to a stimulus is usually sufficient to bring the subject's behavior under the control of changes in that stimulus—provided it is within the capacity of the organism to respond to the given stimulus changes. However, note that the animal does not have to be trained specifically on the dimension that controls its behavior in the test. The birds' response rate changed with tone frequency, yet training was with tone versus no tone.

Is differential reinforcement necessary? In the wavelength generalization study first mentioned, no explicit differential reinforcement was provided—no contrast of occasions during which reinforcement was available with those when it was not. This suggests differential reinforcement is sometimes not necessary, yet there are ways in which such training could have influenced the wavelength experiment nevertheless. For example, perhaps past training with different colors might be influencing the birds' response. Peterson (1962) raised ducklings in yellow sodium arc light (589 nm) so that they never had an opportunity to discriminate one wavelength from another. Given key-peck training and testing as we have described, these ducklings gave flat gradients; their behavior was not affected by wavelength changes. Another group of ducklings reared in normal illumination did give gradients much like the wavelength gradients given by the pigeons. Though the evidence is still mixed, this and a few similar experiments suggest that some kind of differential training may be necessary if a previously neutral stimulus is to control behavior. It should not be forgotten, though, that the unlearned eliciting properties of certain stimuli may control behavior without any history of differential reinforcement.

Generalization among complex stimuli

The old notion of generalization as a "spread

of association" tended to make people think only in terms of tests based on a few simple continua such as intensity or frequency. Stimulus classes, however, may be defined in many ways, and students of generalization have begun to explore some classes defined in more abstract terms. This is really the same thing as studying "concepts," for a concept can also be defined as a class of events occasioning a common response. Because concept learning is considered elsewhere (p. 785), we now look only at an example that relates closely to other generalization research. This is an experiment of Honig (1965), which established "stimulus difference" as a dimension. He trained birds to peck the right one of two keys if both keys were lighted by the same wavelength, but the left key if the wavelengths differed. Each wavelength appeared equally often on both keys, and each was paired equally often with itself and with a different wavelength, so the birds could not learn which key to peck simply by following any particular color or key. They had to learn, as it were, the "color same" and "color different" concepts. Honig collected regular gradients along the dimension of wavelength difference. When the wavelengths on the two keys were physically adjacent on the wavelength continuum, the bird pecked mostly at the "same" key. With larger and larger differences, more and more pecks went to the "different" key. Such experiments suggest that the generalization procedure may be profitably used to find out about animal cognition and perception, as well as to study learning and sensory problems.

Stimulus control is often tested in complex cases where the nature of the stimuli makes the usual kind of generalization experiment impossible. Various aspects of the stimulus may be changed one by one, to see which is effective. For example, Reynolds (1961) reinforced two pigeons for pecking at a white triangle on a red background, and extinguished responses to a white circle on a green background. The birds quickly learned the discrimination, pecking rapidly at the triangle on red and not pecking at the circle on green. What was the controlling stimulus? Reynolds presented the components separately to find out. A triangle on a dark key, a plain red key, a circle on a dark key, and a plain green key were exposed successively. One bird pecked only at the triangle, and not at the red key nor the other stimuli; the other bird pecked only at the red key but not at the triangle nor the other stimuli. Thus, form controlled the response in one case, color in the other, and prior to the tests, it would have been impossible to predict which would be effective.

As we see in more detail shortly, effective stimuli sometimes are not simple, absolute properties of the physical situation. For example, one of the most effective stimuli can only be described as "novelty" or "change"—concepts that certainly go far beyond any specific set of environmental conditions. Many animals "freeze" when a strange event occurs, though if the event becomes common, they may come to ignore it completely. D. O. Hebb (1948) has been one of those who stress the importance of such stimuli and the processes they suggest.

Transposition A fundamental problem of discriminative control has been whether the stimuli are best defined in relational terms ("brighter," "larger") or absolute terms ("brightness *X*," "size *Y*"). A complex generalization test called the "transposition experiment" has been used to help clarify this matter. An example will illustrate this method. The subject first learns to discriminate between two stimuli on some continuum, such as intensity or size; for example, the darker or the larger of the two may be correct. Later, new stimuli from the same continuum are presented, but these bear the same relation as did the training stimuli. In this test, the subject often responds on a relational basis. For example, a rat might continue to choose the darker or the larger stimulus in the transfer task, even though it has never seen that particular stimulus before. Even the formerly correct stimulus may be avoided in the new

situation if it fails to bear the proper relation to the new display. For example, suppose that a gray stimulus was the darker, and correct, stimulus in original learning. In the transfer test, it becomes the lighter, by virtue of being paired with a still darker stimulus. Subjects show transposition if they choose the new, "darker" stimulus.

At first glance, the behavior described above appears to violate the principle of generalization, which predicts that either the previously reinforced stimulus, or the one most similar to it, would be chosen in the transfer task. The Gestalt psychologist Wolfgang Köhler was perhaps the first, in 1918, to point out that the transposition phenomenon creates difficulties for a simple stimulus-response interpretation of discriminative behavior (Ellis, 1938, pp. 217–227). He found transposition in hens, primates, and children. For example, hens were presented grains of food on the darker of two gray papers. In subsequent tests, if the originally positive dark gray were paired with a still darker paper, the hens chose the new and darker stimulus. Köhler argued that they responded according to the relationship ("darker than") between the papers, rather than to the stimuli in isolation. Klüver (1933) replicated the transposition phenomenon, but he also found that it does not always occur. When he presented new stimuli much different from the original pair, his subjects (monkeys) sometimes chose the stimulus most similar to the original positive stimulus, rather than responding according to "relations." The more distant the test stimuli were from the original pair, the more transposition failed.

Figure 17.11. A diagram of hypothetical generalization curves following training with size 256 positive and size 160 negative. By subtracting the negative curve (dotted) from the positive (solid), one arrives at the net response strength associated with each size. Size 655 has the greatest net strength, (6.68), and would theoretically be chosen over size 409 (6.48)—an instance of transposition. Transposition would fail in the extreme case, since 655 would also be chosen over 1049 (2.50), though 655 is the smaller of the two.

Spence (1937) proposed that simple stimulus-response relationships could account for transposition, and the failure of transposition as well, without recourse to new and more complex processes. He did this by reference to two hypothetical generalization gradients as shown in Figure 17.11. The example requires the assumptions that (1) presence of the positive stimulus (in this instance size 256) will produce a certain response strength or excitatory tendency commensurate with the number of reinforcements, while nonreinforced responses will set up inhibitory (or nonresponding) tendencies to the negative stimulus, in this instance size 160, and (2) the organism will respond to that stimulus which has the greater *effective* reaction strength. (The effective strength is the algebraic sum of the excitatory and inhibitory tendencies at each stimulus.) Thus, following simple discrimination training, both stimulus 256 and stimulus 160 will have, by virtue of generalization of both excitatory and inhibitory tendencies, a certain amount of excitation and inhibition associated with them. The *effective* reaction strengths for each will be obtained by subtracting the inhibitory from the excitatory strengths. You can see from the diagram that the organism should choose 256 over 160 when these are presented together (values 4.84 versus 3.16, respectively). More importantly, the simultaneous presentation in a transfer task of stimuli 409 and 256 would predict response to 409 in preference to 256 because the former has the greater net excitatory strength (6.48 versus 4.84). This is the transposition effect. This set of hypothetical

gradients also shows that if stimuli 160 and 100 are presented simultaneously the organism should choose 160, even though this was the previously nonreinforced stimulus. Moreover, if the test stimuli are far enough removed from the original training stimuli, failure of transposition, if not an actual reversal, should occur; simultaneous presentation of stimuli 1049 and 655, for instance, should result in choice of the latter.

Since the Gestalt or relational interpretation cannot easily account for failures or reversals of transposition, Spence's ingenious analysis dealt a telling blow to that position. His views are still perhaps the most coherent account of discrimination phenomena, yet subsequent arguments and experiments have made it clear that they are at best an incomplete account of discriminative processes, as we see in detail below. Spence's gradients were, as he admitted, purely hypothetical. Transposition cannot be predicted from gradients of certain other shapes (those proposed by Hull, 1943, for example), and it has proven impossible to predict such phenomena consistently from empirical gradients collected in recent years (Hanson, 1959). Furthermore, more sophisticated types of discrimination and generalization that have been studied, such as Honig's (1965) generalization along a continuum of stimulus difference cannot be handled by Spence's analysis. The possibility of mediational processes further complicates the issues. In Spence's own laboratory, for instance, Kuenne (1946) found that young children, who do not verbalize relationships among stimuli very well, behave rather like infrahuman organisms in that transposition fails with increasing distance from the training stimuli. In older children, however, "relational" responding occurs even on far tests. Other studies with children (Alberts & Ehrenfreund, 1951; Hunter, 1952; Stevenson & Bitterman, 1955; Stevenson, Iscoe, & McConnell, 1955; Reese, 1961) have supported this now well-established phenomenon.

Zeiler (1963, 1967) has proposed a new theory to explain transposition that makes "relational" ideas more explicit than previous discussions. The theory assumes that training stimuli generate a background or "adaptation level" (p. 59). The reinforced stimulus makes a certain ratio with this level, and this ratio dictates the choice made during transposition tests. During these tests, the adaptation level is shifted in the direction of the set of test stimuli, and this in turn produces a shift in choice. This ratio theory predicts the troublesome finding of transposition on near tests but absolute choice on far tests. (For a complete review of the transposition literature on both animal and human subjects, and of the theories invoked to account for transposition, see Reese, 1968.)

Effective Cues During Learning

The presolution period: "hypotheses" Behavior changes systematically over the course of discrimination learning, and these changes may help to reveal what the subject is responding to as learning proceeds. Even before any apparent stimulus control appears, animals usually do not behave randomly. In this "presolution period" subjects may show predispositions that seem genetically determined; rats, for example, will tend to choose dark alleys in preference to brightly lighted ones. In many cases that involve a spatial choice, such as that between two doors or two levers, subjects show "position habits," consistent preferences for one side or the other. Some of the behavioral consistencies prior to solution were catalogued by Krechevsky (1932a, b) and Tolman and Krechevsky (1933). These authors suggested that even inarticulate organisms such as rats develop "hypotheses" concerning the solution of the problem at hand, and that sometimes, one hypothesis after another is tried until the correct one is adopted and controls subsequent choice. For example, Krechevsky (1932a) presented records of individual animals making 40 responses per day in a situation where the positive cue was a hurdle that had to be jumped to enter the alley leading to food.

This hurdle was placed on the right in half of the trials and on the left in the other half. The rats first developed a position habit, taking the right-hand alley almost every time for several days; thus, they responded to the reinforced hurdle alley only about half of the time. Subsequently, the position habit declined and correct choice (hurdle) rose to 100 percent. Once an incorrect hypothesis was abandoned and the consistently reinforced hypothesis was adopted, the animals quickly reached the discrimination criterion.

To explore the nature of presolution behavior over a long period, Krechevsky (1932b) gave his animals an insoluble discrimination problem. Two possible cues were always present, left versus right position, and dark versus light stimulus, but reinforcement was not associated consistently with either cue. Thus, the rats could reach food on only half the trials. (This procedure was also used by Maier and his colleagues to study fixation behavior [p. 791].) Again, the rats developed consistent patterns of behavior with respect to one or another of the cues. You should bear in mind that the use of the term "hypothesis" in these experiments need not imply complex thought processes; it is simply a name for the behavioral consistencies observed. Discrimination training may in many cases be considered partially a process of getting the subject to abandon such persistent behavior patterns when they are nonadaptive (Harlow, 1959).

Reversal learning In many cases, behavioral consistencies ("hypotheses") are inadequate to reveal what aspects of the environment are controlling behavior early in learning. The so-called "cue-reversal technique" was introduced by McCulloch and Pratt (1934) to gain more information on this matter. Rats learned to pull in a food tray to their cage by a string. They were then shown two trays, side by side, each attached to a string, one tray weighing three times as much as the other. Food was put in the lighter tray early in training but in the heavier tray later. For one group, the tray associated with food was reversed as soon as the individual rat began to improve its score (after 84 trials, the median), and for another group after only 28 trials, long before the first signs of learning were observed. For the control group the food was put in the heavier tray from the start. The results showed that the more trials the rat had when the food was in the light tray, the longer it took to reverse and learn to select the heavy tray. For the three groups, the number of trials required during the second period in order to achieve the criterion of correct responses on 75 percent of the trials was 166, 126, and 96, respectively. This result tended to support the Hull-Spence assumption regarding continuity of training effects during the presolution period: The animal appeared to "learn something" even before its score improved (for more on continuity, see page 773).

Spence (1945) and Ehrenfreund (1948) used the technique of first rewarding animals for developing a position habit. Then, when the animals were consistently responding to just one side, nonpositional positive and negative cues were introduced for a number of trials. Finally, these nonpositional cues were reversed until the animals had attained a high criterion of performance. Ehrenfreund used upright and inverted triangles as the nonpositional cues. Following initial training in which a position habit was induced, the triangle in one orientation was consistently reinforced for 40 trials, not enough to cause an improvement in performance. Finally, the triangle cues were reversed. A control group was given an insoluble problem during the presolution training; they received food half the time for responses to one triangle and half the time for responses to the other. It was reasoned that the control group should start its final training with no predisposition in favor of either triangular cue, whereas the experimental group should constitute a "reversal" condition. It turned out that the experimental group took an average of 63 trials to master the reversed

cues, whereas the control group required only 37, a significantly lesser number. Ritchie, Ebeling, and Roth (1950) produced essentially the same finding in a similar experiment. These findings support the notion that presolution trials do affect subsequent discrimination.

The reversal problem in discrimination learning also has implications for the study of verbal or symbolic processes, as an example will illustrate. The subject views two stimuli, presented simultaneously, that vary both in brightness and in size. A large black square may be presented with a small white square on one trial, and a large white square with a small black square on the next trial. The larger square is reinforced, regardless of brightness. From training in such a task, the subject learns to select the larger stimulus and to "disregard" brightness, which is reinforced only 50 percent of the time.

Subjects so trained now go on to a transfer task with the same stimuli, but with new reinforcement conditions. A "reversal shift" is produced, like that previously discussed: The smaller of the squares is made correct on each trial, rather than the larger. To achieve a "nonreversal shift," reinforcement is shifted to the other stimulus dimension, in this case brightness; either responses to black or responses to white could be selected by the experimenter as the response to be rewarded.

Comparative and developmental psychologists are interested in comparing reversal shift with nonreversal shift performance, because differences appear to be tied to verbal and symbolic processes. Kendler and Kendler (1962) demonstrated that human adults acquire appropriate reversal shift behavior on transfer much more readily than they acquire a nonreversal shift. These authors (1959) also provided data on kindergarten children suggesting that those who are more articulate find the reversal shift relatively easier to make than do those who are less verbal. In contrast, rats characteristically perform somewhat better on nonreversal shift problems than on reversal. The Kendlers suggest that articulate organisms learn during pretraining more than a simple approach to each of the specific stimuli and that they tend to verbalize either overtly or covertly the dimensional regularity of the stimulus situation. Such a subject might verbalize "the larger one" during pretraining, and this verbal "hypothesis" is quickly refuted upon nonreinforcement in the transfer task. Articulate organisms then merely adopt the obverse hypothesis when presented with the reversal shift problem. Such an organism, however, must attend to a different dimension when confronted with the nonreversal shift problem and switch his behavior accordingly.

The explanation given above has not gone unchallenged by other experimenters interested in such two-process theories of discrimination learning, particularly by those writers (for example, House & Zeaman, 1963) who make somewhat different assumptions concerning the mechanisms underlying discrimination learning and the role of observing responses. A complicating factor is that overtraining in the discrimination prior to transfer seems to have a different effect upon behavior in a reversal task than upon behavior in a nonreversal task. (See Shepp and Turrisi, 1966, for a review of the literature relating to this issue.)

Learning sets We have just seen that transfer tasks may be used to find out what an organism has learned in a previous discrimination. Thus far we have dealt only with transfer tests that involve three successive tasks at most. Also, we have dealt mostly with discrimination tasks that involve a relatively protracted period or large number of trials before the organism achieves some high performance criterion on each task. However it is possible to give the subject many discrimination learning tasks one after the other. When this is done, we find that the number of trials necessary for the subject to learn each new task diminishes gradually, even though the various tasks are of about equal difficulty, until new problems are solved after just one
Figure 17.12. Learning set performance of a monkey. These are average learning curves for successive blocks of problems. The more problems the monkey had solved, the faster it learned new problems. (After Harlow, 1949.)

or two trials. Apparently the subject "learns how to learn," a phenomenon that Harlow (1949, 1959) attributes to the formation of so-called "learning sets." Harlow and Harlow (1949) have, in fact, sought to understand the behavioral continuity of species in terms of the rapidity with which they acquire learning sets. These authors argue that apparently insightful behavior, characteristic especially of articulate organisms, is a special case of rapid learning attributable to the previous formation of appropriate learning sets.

In a classic study, Harlow (1949) gave monkeys 312 discrimination problems in the Wisconsin General Test Apparatus. Each problem was presented for 6 trials, the reinforced object being presented randomly at the left and right. Figure 17.12 shows the monkeys' performance over 6 trials plotted separately for blocks of problems. Performance improved remarkably over the series; on problems 1 to 8, the average score rose from the chance level of 50 percent correct to about 75 percent correct during the 6 trials allotted to each problem,.whereas, during the final block of problems almost perfect performance was achieved by the second trial. The trained, now-talented, monkey needed only one nonreinforcement in the two-choice situation to appreciate that the alternative stimulus was the correct one. The learning set phenomenon has been replicated in many studies with primates (Miles & Meyer, 1956; Miles, 1957; Riopelle, 1958), in cats (Warren & Barron, 1956), in rats (Koronakis & Arnold, 1957), and in both normal (Shepard, 1957) and mentally defective (Ellis, 1958; Kaufman & Peterson, 1958) children, in pigeons (Zeiler & Price, 1965), and even in infant monkeys (Harlow, 1960).

An interesting feature of the learning set phenomenon is that it tends to produce a behavioral rank-ordering of primate species that agrees quite well with zoological classifications of phylogenetic standing: the rhesus monkey does better than the squirrel monkey, and the latter better than the marmoset in a series of learning set tasks (Miles, 1957). Similarly, normal children do better than defective children. To examine the relative contributions of intelligence and mental age to learning set formation in children, Harter (1965) used a factorial design involving three levels of IQ (70, 100, 130) and three levels of mental age (5, 7, 9). She gave all subjects ten 4-trial discrimination tasks daily until a performance criterion was reached. Her results demonstrated clearly that both mental age and intelligence were important determinants of learning-set performance, whereas the contribution of chronological age per se was negligible.

Paradoxically, it is not clear what the organism is learning when he is learning to learn. If generalization is involved, it is clear that this is generalization of a special kind, for the phenomenon occurs even under conditions in which the stimuli from task to task are made very dissimilar. In fact, Riopelle (1953) has suggested that the *specific* transfer of response from one cue to another must be *minimized* for a high level of performance to occur. In a sense, the organism must inhibit specific-cue generalization and perhaps adopt a generalization rule of another sort. Another experimenter (Warren, 1954)

has suggested that the type of generalization involved may be progressive appreciation that past learning does not count for much in the new settings! Equally plausible is the proposition that the "rules of the game" are the important features learned. For example, there is no reason why an animal should at the outset of a series of learning-set problems respond as if the experimenter will consistently reinforce one of two simultaneously presented stimuli—he must learn this, and it is only after this consistency has been learned that the animal will respond appropriately to its presence. Similarly, the animal must learn the consistency of the experimental arrangements with respect to alternativeness; if the circle is not correct on trial 1, then the triangle will be correct on trials 2 through 6.

We may anticipate here one aspect of Spence's theory of discrimination learning. That theory proposes that the effect of a given nonreinforcement on the future strength of a given response is greater later in training than earlier. The assumption is that a high-probability response accrues greater inhibition after a nonreinforcement than does a low-probability response. Suppose that late in a series of discrimination tasks the strengths of the initial responses to either of the alternative stimuli (even on the first trial) are greater than the strengths were earlier in the learning-set tasks. It would follow that the effect of a given nonreinforcement late in training will be greater than earlier. The learning-set phenomenon may be deduced from these assumptions, which are made more reasonable by the observation of decreased latencies of response with increasing experience in the learning set series.

Attention and Overt Selective Processes

Such phenomena as generalization, transposition, and reversal indicate that, at a given time, behavior is controlled only by certain aspects of the subject's environment. So far, though, we have said little about the selective process itself. When humans "select" perceptually, they may do so covertly—as when they pick out a friend's voice amid the babble at a party. As yet rather little is known about the way such mechanisms work. (For a full discussion, see Deutsch and Deutsch [1963].) However, overt responses are often involved in attending. We move our eyes to fixate an object of interest, sniff perfume, or reach for a fabric the texture of which we wish to examine. Such behavior can also be seen and studied in animal subjects. For example, an animal often hesitates when it confronts a choice. *Vicarious trial and error* behavior is the name given to the observation that the rat peers back and forth between the alternative doors of a jumping stand, or the arms of a maze. Later (p. 784) we shall see in more detail what use theorists have made of such observations.

Instead of simply waiting for observing behavior to occur naturally, some experimenters have attempted to condition and study it directly. For example, in an experiment by Ziegler and Wyckoff (1961), pigeons pressed pedals to expose discriminative stimuli on a pair of response keys. One experiment compared the behavior of birds that could expose the stimuli in this way to that of birds whose pedals did nothing. The birds with the inoperative pedals had discriminative stimuli projected on their response keys throughout each 40-second trial, while the other birds viewed only two identical white keys unless they pressed the treadle. If the keys were white, reinforcement was available for pecks on one key just as if discriminative stimuli were present. The stimuli simply indicated which key was correct.

Ziegler and Wyckoff found that the birds with ineffective pedals spent only about half as much time on the pedals as did the group of observing-response birds. Some birds in the latter group failed to learn the stimulus discrimination well, and these also failed to press the treadle as much as the others. Why did the "observing" birds learn to press the treadle? Wyckoff hypothesized (1952) that the appearance of discriminative stimuli reinforces observing responses to the extent that

the subject has learned to respond differently to the discriminative stimuli. Once the observing-discrimination process gets going, it is easy to see that a circular effect could strengthen it. As the discrimination improves, observing is reinforced further, and as observing becomes more probable the subject has more and more chances to make the correct discriminative response. We return to some of these matters when we consider mediational processes below (p. 779).

DISCRIMINATION LEARNING THEORIES

When we considered effective cues in the last section, we mentioned at times what the results might imply about underlying discriminative mechanisms. In this section we consider such mechanisms in more detail. Because a great deal has been written about these matters, we have chosen one relatively formalized and influential theory of discrimination, that of Spence (1936, 1937), to illustrate the role that theorizing has played in this area. We look at the postulates of Spence's theory, controversies into which these postulates led when they conflicted with other theories, and some recent work related to concepts important to the theory.

Spence's theory Spence's discrimination learning theory (1936, 1937) is in the systematic tradition of Clark Hull, who described Spence's contribution in this area as an ". . . extension and formalization of Pavlov's analysis of discrimination" (1952, p. 59). The Spence position capitalizes heavily upon Thorndike's Law of Effect, as the postulates of his system show:

(1) Any response followed by reinforcement in the presence of a stimulating situation will produce an increment in the tendency for that response to occur upon subsequent presentations of the same stimulating condition. That is to say, associative or habit strength is a function of reinforcement trials.

(2) Any response occurring in the presence of a stimulating situation and followed by nonreinforcement leads to a decrement in the associative strength between that stimulus and that response.

(3) The *effective* associative strength between a given stimulus and a given response is a function of the increments and decrements accruing to that S-R relationship resulting from the aforementioned reinforcements and nonreinforcements. Specifically, the excitatory increments and inhibitory decrements summate algebraically to yield the resultant associative strength.

(4) On any given trial, the amount of excitation accrued as a result of reinforcement is determined by a bell-shaped function, whereas the amount of inhibition resulting from nonreinforcement increases linearly with trials. Thus the effect of a given reinforcement or nonreinforcement depends upon the current strength of the response tendency. The least amount of excitatory strength is added at the beginning and end of the learning function. The least amount of inhibition is added at the beginning and the greatest amount of inhibition at the end of the learning function. Because observed performance depends on the sum of excitation and inhibition, these assumptions predict that performance over trials will follow an ogival (S-shaped) function.

(5) Both excitation and inhibition accrued through reinforcement and nonreinforcement will tend to generalize to stimuli similar to the stimulating situation present at the time a given response is either reinforced or not. This generalized excitation and inhibition is greater for stimuli physically closer to the training stimulus than for those farther away on the stimulus continuum.

(6) In situations where more than one associative connection is evoked, that response with the greater effective associative strength will tend to occur. This postulate introduces the assumption necessary for deducing performance in a competing-response situation characteristic of discrimi-

nation learning; all of the other postulates refer to the strength of one response in a given stimulating situation.

(7) Finally, the total effective excitatory strength of a stimulus complex will be the sum of the separate effective excitatory tendencies accruing to the component stimuli as described above.

In order to get from the theoretical postulates to actual behavior, it is necessary to make certain other connecting statements. For example, the effective associative strength relative to a given stimulating situation is revealed in such response parameters as amplitude, probability, latency, and so on. Similarly, there are many problems relating to the definition of the stimulating situation. For example, are we to regard a stimulus as any object or event physically present at the time that the organism makes a response, or must we not be rather more specific and indicate those precise stimulating conditions toward which the behaving organism is attentive or which he is perceiving in some way? However, these matters of definition and method do not constitute assumptions or theoretical imperatives of the same class as those described above.

Absolute vs relational theory Spence's theory, just outlined, is sometimes called an "Absolute Theory" because it assumes that effective cues are identified with specific stimuli present at any given moment. Lashley, on the basis of his extensive research on discrimination learning in rats, particularly in the jumping-stand situation, formulated a rather different set of propositions regarding choice behavior in conflict situations. His view is an example of Relational Theory, for he assumes that effective cues may include relations among, and selections from, available environmental stimuli. The essence of his theory can be distilled from three of his major works (1938, 1942; Lashley & Wade, 1946). Concerning the discrimination of differential visual stimuli, such as geometric figures, he said: "Where the pattern contains many items, the animal solves the problem by disregarding most and reacting to a part-figure" (1938, p. 160). Later (1942, p. 242), the basic postulates were given as follows:

> (1) When any complex of stimuli arouses nervous activity, . . . certain elements or components become dominant for reaction while others become ineffective. This constitutes a "set" to react to certain elements.
>
> (2) In any trial of a training series, only those components of the stimulating situation which are dominant . . . are associated. Other stimuli which excite the receptors are not associated because the animal is not set to react to them.

These postulates show that Lashley's theory is of a perceptual kind, for selective attention during learning is important: the effective cues are those to which the organism is "set" to respond. For Spence, all cues impinging on the receptor organs of the learning animal are pertinent. From this difference sprang the so-called "continuity versus noncontinuity" issue. Spence's views imply that the acquisition of discriminative control is continuous, with increments and decrements in response strength accruing, as specified in his postulates, to each stimulus present on each trial of a learning task. In contrast, Lashley's postulates implied that a particular unattended stimulus might acquire no control for many trials, and then suddenly acquire control as a result of a shift in attention.

Lashley and Wade (1946) tested these views in the following way. One group of rats was taught to jump at an 8-cm wide circle and to refrain from jumping at a black square. Another group was taught to jump at a 5-cm wide circle, with the plain black square again the negative stimulus. Next, both groups learned a simultaneous discrimination between the 8-cm and the 5-cm circles, with the 8-cm circle reinforced for both groups. Lashley and Wade reasoned that the original training should have little effect on the second task, for the rats would have had no reason to notice the size of the diameter of the circle when it was paired with the black

square. Absolute theory, in contrast, would predict that the rats trained originally to the 8-cm circle should do better in the second task because they had already accrued response strength to the 8-cm stimulus before they started the second task. The opposite occurred, for Lashley and Wade found that the rats originally trained with the 5-cm stimulus learned the second task more rapidly. In other words, the results were contrary to the predictions of both the Absolute and the Relational Theories. However, replications under somewhat altered conditions (for example, after eliminating the punishment characteristic of the Lashley jumping-stand procedure) have for the most part failed to corroborate the Lashley-Wade findings; rather they have supported the Absolute Theory (Grice, 1948b). Although there are now very serious doubts about their generality, the Lashley-Wade findings have at least encouraged caution in applying assumptions derived from situations involving no punishment to procedures where punishment is a significant feature.

The Lashley-Wade experiment illustrates the assumption, implicit in Relational Theory, that subjects will not learn about properties of a stimulus (like circle size) unless given an opportunity to compare stimuli differing in the relevant property. In a further test of this position (Grandine & Harlow, 1948) monkeys first were taught to respond to a single reinforced stimulus; subsequently, they were tested on a simultaneous discrimination with the originally reinforced stimulus presented along with a new stimulus differing in either height or brightness. Contrary to Lashley's prediction, clear evidence of positive transfer resulted. Despite such data, Warren and Brookshire (1959) have asserted that few studies provide the definitive test with experimentally naive primates that was required by the Lashley-Wade formulation. Warren and Brookshire therefore used monkeys that "had no opportunity to develop comparison behavior in formal discrimination learning experiments before participating in this investigation." Experimentally naive animals made reinforced responses to a single stimulus, and then learned a discrimination involving the rewarded stimulus and a new one. For half of the subjects, the previously rewarded stimulus was correct. For the other half, the new stimulus was correct. Again, the evidence weighed against the Lashley-Wade proposition, for fewer errors were made by the animals required to choose the stimulus reinforced in single presentations.

Lashley's requirement that animals must not have had prior experience with making comparisons in discrimination situations is very stringent, and it is unlikely to be truly met by most laboratory animals. It appeared desirable, therefore, to do an experiment in which stimulus comparison was actually encouraged, for that should, according to the Lashley assertion, produce *better* performance than rewarded experience with single stimuli. Accordingly, Lipsitt (1962) provided 4 groups of 20 children with different pretraining experiences, prior to training in a two-stimulus simultaneous task. Group I received 20 single reinforced presentations of the subsequently positive stimulus; Group II received 20 single reinforced presentations of the subsequently negative stimulus. Group III received 20 trials of comparative experience with the discrimination stimuli, and Group IV received 20 single reinforced presentations to each of the subsequent discrimination stimuli. Group I produced the best subsequent discrimination performance, being significantly superior to both Groups III and IV. Group II was significantly superior to IV but not to III. No reliable difference appeared between the performances of Groups I and II, although the tendency was in favor of Group I. Inasmuch as the two groups with prior experience with both of the stimuli that were to be discriminated tended to do more poorly than the groups given single-stimulus pretraining, these data seem to extend the Warren-Brookshire findings to humans, and to contradict the Lashley-Wade proposition that experience with single stimuli does not

produce transfer to a subsequent discrimination task.

As has been previously indicated (pp. 766–767) the behavior of animals in reversal learning situations is pertinent to the resolution of the continuity versus noncontinuity controversy. According to the continuity position (Spence, 1951, p. 719):

> . . . discrimination learning is conceived as a cumulative process of building up the excitatory strength (habit, associative strength) of the positive cue as compared with the competing excitatory strength of the negative cue. This process is assumed to continue until the difference between the excitatory strengths of the two cues is sufficiently great to offset any other differences in excitatory strength that may exist between the stimulus complexes of which the cues are members . . . As a critical test of the two opposed theories an experimental design has been employed in which the significance of the stimulus cues during a preliminary period of trials, in which the subject is responding with some irrelevant hypotheses, is the reverse of that used in the subsequent problem (i. e., the positive cue is made negative, and vice versa). According to the non-continuity theory this preliminary training should have no effect on the subsequent learning of the reverse problem. In contrast, the implication of the continuity theory is that the learning of such a reversed group would be retarded as compared with a control group that did not have such initial reversed training but instead was given a 50-percent reinforcement on each of the relevant cues for the same period of trials.

Spence (1951) pointed out that Krechevsky's data (1938) on this issue showed that one group given 40 preliminary trials prior to reversal transfer supported the continuity theory but that another given 20 preliminary trials supported the noncontinuity position. Spence suggested that in the beginning of training on a jumping-stand apparatus, the animal is probably attending most to the bottom of the stimulus cards near the position where it must terminate the jump. This suggests that only later in training does the animal truly receive differential stimulation from the positive and negative stimuli. Says Spence:
> The subject must first learn to make the appropriate receptor-orienting acts that will lead to the reception of retinal stimulus patterns that are discriminable. Krechevsky's subjects presumably failed to do this in the 20 preliminary trials but did so in 40 trials. Hence the former group showed no retardation, whereas the latter did (1951, p. 720).

Corroborative evidence was found by Ehrenfreund (1948) by manipulating the heights at which the stimuli were presented in front of the animal relative to his standing position.

Recent investigators have come increasingly to feel that attention factors play such a fundamental role in discrimination learning that earlier statements implying a continuity-noncontinuity dichotomy may be misleading. After reviewing the mixed evidence, Mackintosh (1965) concludes that both extreme positions were wrong: Subjects do not concentrate entirely on one cue or organization at a time, as Lashley's position implies, nor do they respond equally to every available stimulus, as an extreme reading of Spence's position might suggest. He says: "Animals do not classify their stimulus input with equal effectiveness in all possible ways at once, and it should therefore be possible to influence what an animal attends to by appropriate procedures." In short, one may get either "continuity" or "noncontinuity" results depending on the procedures employed, these procedures affecting the results through their control of attention. Other extended arguments on these issues may be found in Osgood's excellent chapter on controversial issues in learning theory (1953, pp. 413–473) and in Spence (1951, pp. 690–729).

Still another account of the mechanisms underlying discrimination learning performance is provided by Harlow (1950, 1959), and is sometimes called "Uniprocess Learning Theory." This theory is based upon analyses of the errors made by animals in the course of discrimination learning. This theory emphasizes the gradual suppression over learning trials of specific types of incorrect responses that reflect "error factors," such as

TABLE 17.1

II	■	□	□	□

stimulus perseveration, response shifts, and position preferences. The analysis of errors in the course of learning is, as Kimble (1961) has pointed out, rather similar to the Kreshevsky analysis of behavioral "hypotheses" and their successive testing and elimination in the course of acquiring the "correct hypothesis."

Simultaneous versus successive stimulus presentation We can further understand the interaction of theory with experiment by considering the way in which Spence dealt with a classic methodological issue. Hunter (1914) had labeled two general methods for stimulus presentation the *successive* and *simultaneous* procedures. These are roughly equivalent to the psychophysical procedures called the "Method of Single Stimuli" and the "Method of Paired Comparisons," respectively. Table 17-1 illustrates the two situations. The stimuli in each instance may be visualized as the doors on a Lashley jumping stand. One door is the positive (reinforced) and the other is the negative (nonreinforced) door on each trial. The sides are counterbalanced from trial to trial, as indicated by I and II. In the simultaneous case, the two discriminative stimuli (here, black and white) are both present on every trial. In the successive case, only one stimulus, black or white, occurs on any trial. It would seem that the subject has an advantage in simultaneous discrimination, for he can compare the alternative stimuli within a single trial. To make such a comparison in successive discrimination, he must compare a current stimulus with his memory of the alternative stimulus from previous trials.

Spence (1936) described simultaneous discrimination learning as the strengthening of a response to the reinforced stimulus until this response tendency exceeds competing tendencies enough to yield consistently correct choices. Thus, in this instance, reinforcement would cause the response to white gradually to become stronger than response to black. Spence assumed that because the tendencies towards the left or right were reinforced equally often, responses based on positional cues would tend to equalize, and being nondiscriminative, these tendencies would ultimately have little effect upon choice. Bitterman and his colleagues (Weise & Bitterman, 1951; Bitterman & Wodinsky, 1953) challenged this interpretation of discrimination learning, arguing that the mechanisms proposed by Spence predict that no learning should occur under the *successive* stimulation procedure, for white, black, left, and right are all equally reinforced in the long run. They reported data showing, in fact, that not only does successive presentation produce learning but rats under some conditions solve successive problems more rapidly than they do if the simultaneous procedure is used. Spence (1952) extended his discrimination-learning theory to account for the solution of the successive problem as a patterned discrimination. He proposed that the organism approaches certain patterns or combinations of reinforced stimulus components, while response to other patterns is not reinforced.

TABLE 17.2

Trial	Procedure			
	Simultaneous		Successive	
I	W, L > +	B, R > −	B, L > +	B, R > −
II	B, L > −	W, R > +	W, L > −	W, R > +

Under this conception, comparison of simultaneous and successive procedures can be made as shown by Table 17.2, where *W* is white, *B* black, *L* left, and *R* right. Spence contended that the successive problem may be predicted as solvable without sacrificing the basic propositions of his theory because responses may be learned to the compounds *BL, BR, WL,* and *WR*. Moreover, he predicted that, contrary to the findings of Bitterman and his colleagues, under at least some conditions, the successive method should produce slower learning than the comparable simultaneous task because the compounds to be discriminated on each trial are more similar (and thus should generate greater competing generalization) than they are in the simultaneous problem. Under the simultaneous procedure, responses to white in one stimulus setting should generalize to white in the other setting; such generalization would hinder acquisition of differential responding in the successive procedure. Spence presented evidence from T-maze experiments that showed the superiority of the simultaneous over the successive procedure.

Theoretical controversy sometimes serves to highlight the importance of previously disregarded parameters, as it did in the experiment discussed above. Spence called attention to the fact that his original discrimination learning theory applied to instances in which the animal must "orient towards and approach the stimulus complex (path, door, alley, window) containing the positive stimulus cue (white, form, etc.) . . ." (1952, p. 89). Under such circumstances simultaneous presentation should lead to faster learning than successive presentation. In Bitterman's procedures, the stimuli were removed from the locus of response, for the animals were presented with the stimuli in the middle section of the Lashley jumping stand, but they had to jump at windows off to the left and right.

The present state of affairs with respect to the simultaneous-successive issue seems to be as follows. When a response is made to the locus of stimulation, the simultaneous method tends to produce better learning than the successive method, but when the locus of responding is to some point removed from the stimulus source, the successive often produces better performance than the simultaneous method of presentation (Bitterman, Tyler, & Elam, 1955). It would appear, however, that the similarity between stimuli interacts with other parameters to determine the rapidity of learning under the simultaneous and successive procedures. Loess and Duncan (1952) have shown that, with highly similar stimuli (difficult discriminations), simultaneous procedures proved better than successive procedures, but when the stimuli were less difficult to discriminate there was no statistical difference between the procedures, although, in fact, the successive method appeared to produce slightly superior results. MacCaslin (1954), using a Lashley apparatus, also showed a superiority of the simultaneous over the successive method when the stimuli were similar, but found no difference under a distinctive-stimulus condition.

In a series of experiments with children involving comparisons of simultaneous and successive presentation procedures, Lipsitt (1961) found the successive procedure to produce better learning than simultaneous presentation when the response was made to buttons removed several inches from the stimulus sources, but showed the effect to be reversed when the children responded directly to the stimulus source. He showed further that this relationship is affected by the degree of similarity between stimuli, for under conditions of high similarity, simultaneous presentation provided better learning than successive, whereas if highly distinctive stimuli were presented, this difference disappeared or resulted in an inversion, with the successive procedure producing superior results. Thus, a high degree of similarity between stimuli and a response locus close to the stimulus source tends to maximize the superiority of simultaneous over successive procedures, whereas under opposite condi-

tions the successive method tends to become superior. Other experimental manipulations that tend to depress discrimination learning generally, such as increasing the delay of reinforcement or separating the stimuli in space or time, might have similar effects on performance in these two tasks.

The Problem of "Inhibition"

Discriminative control, in Spence's theory, can largely be seen as an interaction of excitatory tendencies, associated with reinforcement, and inhibitory tendencies, associated with nonreinforcement. In this regard Spence follows Pavlovian theory; the basic idea has been quite popular with other theorists as well. Recent work, much of it done with pigeons in free-operant situations, has added substance to the notion of inhibition. This work has also suggested that an inhibitory process need not always be involved in discriminative control in the manner that has often been supposed by theorists.

Errorless discrimination training Let us consider for a moment different ways in which discriminative behavior may be brought about. One might choose among many procedures and still use "differential reinforcement" in the sense that behavior would be reinforced differently in the presence of the two stimuli. In the most common free-operant discrimination procedure, responses to one stimulus (the "S^D," or "S+") bring reinforcement, often on an intermittent schedule. Responses to another stimulus ("S^Δ," or "S−") yield no reinforcement, and sometimes such responses prolong the duration of the S−. For example, a monkey might press a lever whenever a lamp glows above it (S+), such responses producing a food pellet once a minute on the average. When the lamp is out, pressing the lever produces no food. Usually in such a case the monkey responds many times early in the experiment, both when the lamp is on and when it is off. As discrimination develops, responses when the lamp is off gradually cease.

A second method avoids responses in the S−, and thus it has come to be called "errorless" discrimination training. The experimenter starts with a situation in which some discriminative control already exists, a "very easy" discrimination task, and gradually works toward a more exacting task. This general idea has been used for many years, but its importance has only recently been fully recognized, largely as the result of a series of experiments by Terrace (see Terrace, 1966a). One example will illustrate the basic features of the procedure. Pigeons were trained to discriminate a red response key (S+) from a green key (S−) without ever making responses to S−. First, the S+ came on for 30-sec intervals, and in its presence pecks at the key brought food on a variable interval schedule. After the birds were responding regularly, the green S− was introduced in three stages. First, interspersed with S+ presentations, the key went dark briefly (5 sec) and then S+ reappeared. Then, over successive presentations, the dark period was increased gradually to 30 sec. During this time, the pigeon kept pecking when the S+ was on, but withdrew from the darkened key. In the next training stage the S− duration was again reduced to 5 seconds, but a very dim green light was turned on behind the key during this time. The intensity of this light was gradually increased over successive presentations. Finally, with the green S− now up to full intensity, the duration of the S− was increased from 5 to 30 sec. Later S+ and S− were both increased to 3 min.

Terrace found that birds trained in this way responded little or not at all to S−. Birds that did not have the final S− gradually introduced, and birds that first saw the S− only after considerable experience (14 sessions) with the S+ alone all gave many responses to the green S− before finally learning the discrimination. Terrace trained birds that had learned the red-green discrimination without errors on a more difficult discrimination, still without allowing errors. They were trained to peck at a vertical white line but not at a hori-

zontal white line. This was done by first superimposing the lines on the key colors already learned (vertical line on red S+, horizontal line on green S−), and then gradually fading out the colors.

Our reason for studying the errorless discrimination method is not simply because it is an efficient method for sharpening discriminative control, although such a gradual introduction to a difficult discrimination may be very helpful. More important is the fact that discriminations learned through errorless training seem to differ from those learned through the use of extinction or punishment, and the differences give some hints of the behavioral mechanisms involved. Before getting into these differences, however, let us look at some interesting outcomes produced when ordinary (that is, errorful) discrimination procedures are used.

Behavioral contrast Pavlov noted long ago (1927) that when positive and negative conditioned stimuli were presented one after the other in a discrimination experiment, the conditioned response to the positive stimulus was greater just after the negative stimulus had been presented, and often the response to the negative stimulus (if there was any) was less if the negative stimulus was presented just after the positive (see "induction," p. 710). These observations are strikingly parallel to contrast in sensory systems, which is often attributed to the generation and release of inhibitory effects.

A somewhat similar phenomenon has recently attracted interest in operant experiments. An experiment of Reynolds (1961) provides a good example. Pigeons were trained to peck a key with reinforcement on a variable-interval 3-min schedule. Sometimes the key was red, sometimes green, but at first these colors were of no significance, and the birds pecked equally at the two colors. Then a discrimination was programmed, such that the birds were still reinforced on the same schedule for pecks at the red key, but were extinguished for pecks at green.
Figure 17.13. Behavioral contrast in one pigeon. At left, pecking yields reinforcement at the same rate (VI 3 min) whether the key light is red or green. In the center, green goes unreinforced and pecking to red speeds up, though red is reinforced no more frequently than before. At right rates to red and green converge again with equal reinforcement. (After Terrace, 1966; data from Reynolds, 1961.)

Now, according to older notions of discriminative mechanisms, we might predict the following: The rate of response to green should decline, certainly, because no food is forthcoming for responses in green. What about the rate of response to red? This might also go down, for the bird is getting less reinforcement overall than before. More important, theory suggested that inhibition now building up in association to the green S− would generalize to the red S+ and cause some reduction of rate to that stimulus (see Spence, 1937). Just the opposite happened. As the discrimination was acquired, the rate to the red S+ rose as the rate to the green S− declined. The rates reversed their trends when both colors again were correlated with reinforcement (Figure 17.13). This contrast effect has appeared in a number of experiments with response rate; response latency also has been shown to change in similar ways (Jenkins, 1961). The similarity of this effect and "reinforcement contrast" has already been noted (p. 641).
Figure 17.14. Generalization peak shift in two groups of pigeons given discrimination training on a wavelength continuum, compared to a control group with no discrimination training. All birds were reinforced for pecking at the 550 nm stimulus (S+). The group that received no discrimination training (solid curve) gave a curve with a peak at the S+. The group given discrimination training with an S− of 570 nm yielded the curve peaked at 540 nm, while the gradient of birds trained with an S− of 555 is still further displaced. (After Hanson, 1959.)

Generalization gradient peak-shift Related to behavioral contrast is another experimental result of ordinary discrimination training "with errors." As we have seen, the generalization gradient is usually obtained in operant experiments by training the subject to respond in the presence of a particular stimulus and then, during an extinction session, varying some aspect of that stimulus while recording the number of responses emitted in the presence of each test stimulus. The resulting gradient, while not necessarily symmetrical, ordinarily has a peak at the stimulus value to which the subject was exposed during training. However, this is not the case if the subject is originally trained not on a single stimulus but on a discrimination that involves the stimulus dimension later to be tested. When such discrimination training is given, the gradient resulting from a generalization test is displaced away from the S− used in the discrimination. The classical demonstration of this is shown in Figure 17.14. Here, in an experiment by Hanson (1959), the solid curve shows the generalization gradient on a wavelength continuum from pigeon subjects after ordinary single stimulus training. The other gradients come from other groups of birds that received, before testing, discriminations with the same stimulus as S+ (550 nm), but various other stimuli as S− in a successive discrimination procedure. Note that not only are responses lacking to the S− wavelengths, but that most responses are given not at the wavelength used for training but at other wavelengths displaced to the side opposite the S−. Note also that these post-discrimination gradients are higher than the control gradient; this is another instance of the behavioral contrast phenomenon.

Two kinds of discriminative control? Both behavioral contrast and the peak shift were found to follow ordinary discrimination training done "with errors." However, neither of these effects seems to arise if the discrimination is learned without errors, according to recent experiments (Terrace, 1963a, 1964). That is, if pigeons are trained to respond to green and not to red in such a way that many responses to the red S− occur before the discrimination is learned, they speed up in the green S+ (behavioral contrast) and testing for generalization with various stimulus wavelengths reveals a peak shifted away from the red end of the spectrum. If the birds are trained to discriminate by the errorless method, they do not speed up in S+, and the generalization gradient peak falls at the same green on which the birds were trained.

These observations suggest that two different sorts of discriminative control arise from the two kinds of training. Do any other observations suggest such a difference? Terrace (1966a) lists several. For one thing, pigeons act quite differently during training in the two cases. The bird learning without errors simply settles down quietly when S− appears and waits for S+ to return. The bird learning "with errors," in contrast, often reacts emotionally to the S−, flapping its wings,

turning, sometimes jumping or cooing. It looks for all the world as though the bird were getting a mild shock or some other punishment. This suggests that the S− becomes aversive during training with errors, a conclusion supported by the fact that shock in the presence of a stimulus can produce behavioral contrast and peak-shift (Brethower & Reynolds, 1962; Gousec, 1968).

Another notable difference between discriminations with and without errors lies in the later performance of the subject. Even though responding to S− has been near zero for some time, the subject that learned with errors is apt to give occasional bursts of responses to the S−. The errorless-trained subject never does this unless some change occurs in the situation, such as a too-rapid advance to a difficult discrimination or a period of extinction on S+. If, as a result of such changes, the errorless-trained subject is induced to respond to the S−, all is lost. Even earlier, easier discriminations are upset, and discriminative control is only regained by training with errors.

A final test for differences between the two types of training is in the reaction of trained subjects to drugs. It has been found that certain drugs will disrupt even well-learned discriminations, leading to extensive responding in S−. Testing two of these drugs, Terrace (1963b) collected several thousand responses in S− from each error-trained pigeon with heavy doses, and proportionately fewer with lighter doses. Errorless-trained birds did not give a single response to S− at any dose level.

Observations such as those we have reviewed suggest that there are indeed at least two kinds of response rate decrements involved in discriminative control. It is tempting, and perhaps appropriate, to apply the two labels that Pavlov, Spence, and other theorists have used for many years. The ordinary generalization decrement, where responding diminishes as we move away from the S+, and the decrement in response to the S− in errorless training may be thought to involve only "excitatory" control. Such responding follows the rule: "Respond if S+, otherwise do not respond." The decrement developed by ordinary discrimination training with errors, and presumably by punishment for errors, involves in addition "inhibitory" control. It follows the rule: "Respond if S+, do not respond if S−." Jenkins (1965) states these rules and discusses how we might test to find out if inhibitory control is involved in any given case. It would appear that, with inhibitory control, S− stands out as a "stimulus not to respond to." Where such inhibitory control is absent, an S− is simply one of all the indefinite number of situations that do not prompt the subject to respond. It is a part of the background, as it were. If this is the case, one might expect to be able to measure a generalization gradient around an inhibitory S−; with changes away from a particular value, the "tendency not to respond" ought to diminish. No gradient would be expected for an S− that exerts no inhibitory control for in changing this stimulus we simply move on to another stimulus that is equally "not the S+."

Some gradients of inhibition have indeed been collected around inhibitory S− stimuli. For example, Jenkins and Harrison (1962) set up a discrimination between a pure tone S− and either silence or white noise as S+. Varying the frequency of the tone now *increased* the response rate, which thus made the inhibitory gradient an empirical reality. Terrace (1966b) rounded out the picture by showing that, following errorless training, no increase in responding occurred when the S− was changed. The generality of all these results needs to be established by work with other species and situations, but at the moment the case for separating excitatory from inhibitory control seems rather convincing.

MEDIATION PROCESSES

Thus far we have dealt almost entirely with controlling relations between physical stimuli and responses. We must also appreciate, however, that the choices of both animals and humans are determined in part by responses

themselves, for responses may have stimulus counterparts capable of becoming part of the total stimulus to which the organism responds.

Acquired distinctiveness and equivalence of cues Suppose an animal is taught (let us say by the use of positive reinforcement) to lean a little to the left in the presence of a given stimulus such as a triangle. If subsequently that triangle becomes one of two stimuli between which the animal must choose, the lean may be a factor in the acquisition of differential responding to the two stimuli. Picture an animal that leans to the left in response to a triangle and stands upright in response to a circle when it is first placed in a simultaneous discrimination situation. The animal is likely to engage in appropriate swaying responses as it looks at these two stimuli, with the distinctive leaning to the left becoming part of the stimulus complex with the triangle and the upright stance becoming part of the complex with the circle. Such increased distinctiveness of the circle and the triangle, *mediated* by the organism's responses and the proprioceptive counterparts of these responses, is likely to facilitate subsequent discrimination learning of new responses, such as jumping to the circle and not jumping to the triangle. Such facilitation apparently is quite general, even allowing animals to discriminate more accurately among deprivation and reinforcement conditions (Miller, 1935). This kind of facilitation has been attributed to the "acquired distinctiveness of cues" (Dollard & Miller, 1950, p. 101). The opposite of this phenomenon occurs when the same response and its associated proprioceptive stimulation is first attached to both of the stimuli to be discriminated, thus retarding the learning of a discrimination between these stimuli. This is termed "mediated generalization" or "acquired equivalence of cues" (Miller, 1948). Although these concepts of acquired distinctiveness and equivalence have helped to explicate some animal behavior (Riley, 1968, pp. 58-63) they have been used principally to extend basic stimulus-response theory to encompass the complex discriminative behavior of articulate, symbol-using humans.

A student of Miller, Birge (1941), performed some of the earliest systematic research on mediational phenomena in children. She asked whether a response will transfer from one stimulus to another more readily when those two stimuli have the same name attached to them than when they have different names. She taught third-, fourth-, and fifth-grade children to call two pictures of nonsense animals by one name and two other pictures by another name. Then pairs made up of one picture from each name pair were presented, and the children learned under which of these a piece of candy was consistently hidden. In the third stage of the study, the remaining stimulus picture of each name pair was presented to discover which of the two the subjects would now choose. Most subjects chose the stimulus bearing the same name as that one under which the candy was previously found. This is the result one would expect from the concept of mediated generalization. Birge also showed that when overt verbalization of the names was required during both the candy-finding and test stages, performance was better during the test than when such "overt mediation" was not involved.

Another study demonstrating the phenomenon of mediated generalization, of both a verbal and a motor sort, is that by Jeffrey (1953). He taught preschool-aged children to move a lever in one direction to a white stimulus and in another to a black stimulus. Then some subjects were taught to call a gray stimulus by the name "white" and others to call it "black." After a retraining session in which the subjects again moved the lever appropriately to the white and black stimuli, Jeffrey presented the white, black, and gray stimuli successively and randomly to determine the direction in which the lever would be moved to each of these stimuli. The general finding was that the children who were

given the "white" name for the gray stimulus now moved the lever in the direction appropriate for white, while those taught the name "black" for the gray stimulus moved the lever appropriately for black. Thus the subjects behaved toward the gray stimulus as if it were white or black, depending upon their mediational pretraining. Likewise, children who were taught to turn the handle in a special way for white and a different way for black and then had motor mediational training to make one or the other of these motor responses to the gray stimulus, produced data in the test task comparable to that produced by verbal pretraining.

An interesting adaptation of the acquired equivalence paradigm was made by Eisman (1955) to the area of attitude or opinion formation. Eisman first taught children a different name for each of three white geometric blocks. The children were then reinforced for selecting a particular one from among the three blocks. Following this, they were taught to associate the three names respectively with each of three different colored blocks. When the children were next required to find a reward under one of the three colored blocks, they tended to choose the color with the same name as the previously reinforced white block. Several adaptations of the final testing procedure yielded the same finding. For example, Eisman demonstrated that children would verbalize a preference for a fictitious group of children that had been assigned the color name consistent with the rewarded white-block experience. In several ways, then, it was established that children's color preferences (even for playmates) may be engendered through mediational learning mechanisms. Studies that have demonstrated other facets of the acquired equivalence phenomenon include those by Murdock (1952), Bugelski and Scharlock (1952), and Russell and Storms (1955).

The other side of the mediational coin has to do with the enhanced distinctiveness that results when distinctive verbal labels are attached to stimuli. This has also been studied rather thoroughly in recent years. In a study of both acquired equivalence and distinctiveness, Gerjuoy (1964) used second-, third-, and fourth-grade children to test discrimination following the attachment of either dissimilar-sounding or similar-sounding names to the discriminative stimuli. The expectation was that similar naming would retard, while dissimilar naming would enhance, subsequent learning relative to a control group that was merely required to observe the discriminative stimuli. However, it developed that both of the name-learning groups showed enhanced performance relative to the control.

Such results remind us that if we are to demonstrate that acquired distinctiveness effects in transfer tasks are the result of specific verbal pretraining, it is necessary to rule out the effects of aspects of the pretraining situation other than the simple attachment of discriminative verbal responses to the pertinent stimuli. Sometimes it might be argued that the "real" distinctiveness effect was obtained merely by calling the subject's attention to certain features of the two stimuli. An experiment by Cantor (1955) investigated this possibility. The transfer task was a simultaneous discrimination involving reinforcement for choosing one of two toy cars with different stimuli attached to them. The stimuli were facial drawings of two similar-looking girls. One group of subjects first learned a different name for each of the faces. This was called the "relevant pretraining" group. A second group, called the "attention pretraining" group, learned no names, but received comparable trials in which they were required to look at and point to various facial features, thus committing them to observation of the stimuli to be used in the transfer task. An "irrelevant pretraining" group learned names for an alternate pair of faces. The relevant pretraining group learned the transfer task the fastest, but the other two groups were comparable in performance, indicating that mere perceptual experience with the pretraining stimuli does not produce an effect comparable to that produced by specific distinctive-

ness pretraining. Kurtz (1955) in fact suggested that acquired distinctiveness effects might result as a kind of artifact attributable to the subject's enhanced "observing behavior." The poorer performance of the attention pretraining group in Cantor's experiment relative to the relevant pretraining group tends to negate the Kurtz interpretation in this case.

A study by Norcross and Spiker (1957) further attempted to rule out the "observing response" interpretation of "acquired distinctiveness" effects. The subjects were preschool children and the stimuli used were the same as those used by Cantor. A relevant pretraining group again learned a different name for each of the faces. A second group received discriminative experience with the relevant stimuli but learned no names. Instead, these subjects were given the stimuli simultaneously and were asked to respond "same" or "different"; on some trials duplicate pictures were presented and on others the two transfer stimuli were presented together. This pretraining necessitated discrimination between the stimuli but did not foster the attachment of differential names. A second discrimination group was presented the two stimuli successively during this period; the subjects were merely asked whether each stimulus was the same as or different from the previously observed one. This group was included to preclude any possible argument that the successive stimulus presentation method tends more than the simultaneous to induce appropriate observing behavior on the part of the subjects. The results of this experiment clearly indicated that the discrimination groups did not differ reliably from one another, but the relevant pretraining group did perform significantly better than those two.

Spiker provides an incisive review of these and other related studies. He says (1963, p. 259):

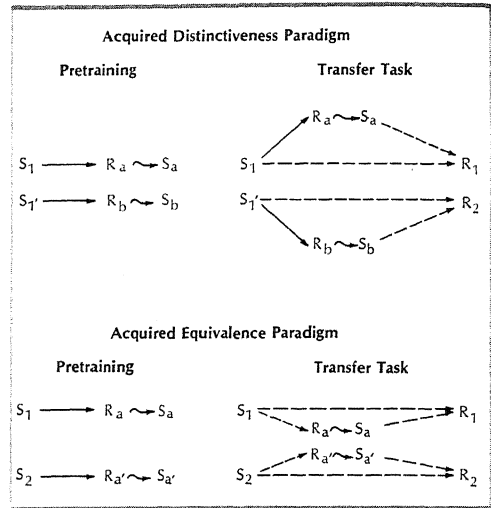
> The results of these experiments suggest that there is facilitation resulting from prior learning of distinctive names for stimuli that cannot be attributed to warm-up, learning-to-learn, or observing responses. Apparently, there is something about the learning of names, per se, that results in the subsequent facilitation. To the extent that other implications of the acquired distinctiveness of cues hypothesis can be experimentally confirmed, the hypothesis may be used as a plausible explanation for these and similar findings.


Figure 17.15. The acquired distinctiveness and equivalence processes. See text. (After Spiker, 1963.)

Figure 17.15 symbolizes, in stimulus-response terms, the presumed mechanisms underlying the facilitation of transfer in acquired distinctiveness studies, and the deleterious effect upon transfer of acquired equivalence pretraining. The diagrams suggest that acquired distinctiveness training probably works best with relatively similar stimuli, symbolized as S_1 and S_1', whereas acquired equivalence pretraining likely has its greatest effect with relatively dissimilar stimuli, symbolized as S_1 and S_2. The subscripts associated with R reflect the relative distinctiveness of the responses being associated during the pretraining period. The diagram indicates that the response-produced stimulation, associated with R_a and R_b in the acquired distinctiveness task, enhances the effective distinctiveness of S_1 and S_1' during transfer. Similarly, the response-produced stimulation from R_a and R_a', in the equiva-

lence task, diminishes the effective distinctiveness of S_1 and S_2.

In a study that sought to examine acquired distinctiveness and equivalence simultaneously in the same subjects, Norcross (1958) conducted two experiments that provided control of the variables during the sessions for warm-up and learning to learn that might obscure true mediational effects. In the transfer task, kindergarten children were required to press one of 4 buttons to each of 4 pictorialized faces presented successively, 2 female and 2 male. In pretraining, the subjects learned similar names ("zim" and "zam") for one pair of faces and dissimilar names ("wug" and "kos") for the other pair. During transfer, the subjects overtly verbalized the stimulus names before responding to the buttons. As expected, performance was better when the subjects were presented the faces that were differently named than when they were presented the similarly named ones.

The hypothesis that observing responses underlie the enhanced "acquired distinctiveness" effects (Kurtz, 1955) cannot account for the differences obtained on the similarly named and dissimilarly named stimuli in such an experiment as that of Norcross, for the subjects had equal opportunity to develop appropriate observing behavior for both types of learning pairs. Nevertheless, we cannot infer from the results of such a study whether both acquired distinctiveness and equivalence have occurred or whether just one of these effects was responsible for producing the difference in performance on the two types of pair. In a complex and elaborately counterbalanced experiment, Reese (1960) explored the effects of pretraining with distinctive names, similar names, or no verbalization associated with the stimuli to be used in the transfer task. On the basis of the results obtained, Reese suggested that (1) poorly learned names, regardless of how distinctive or similar they may be, will produce interference in a transfer task, and (2) both distinctive and similar names, if thoroughly learned during pretraining, will produce transfer facilitation.

Although all of the mediation studies considered thus far have used human subjects, the acquired distinctiveness and equivalence phenomena are not necessarily limited to articulate organisms. On the contrary, an extensive series of experiments by Lawrence (1949, 1950), Bauer and Lawrence (1953), Lawrence and Mason (1955), and Goodwin and Lawrence (1955) suggest that mediating processes of the sort discussed here are evidenced by rats. This is made more plausible by noting that, in humans, motor mediation works essentially the same as verbal mediation (Jeffrey, 1953). Lawrence proposes that the execution of distinctive responses to differential stimuli yields response-produced stimulation, which in turn facilitates subsequent discrimination learning involving the same stimuli. In one experiment, for instance, Lawrence (1949) first trained animals in a simultaneous discrimination procedure to respond to black versus white visual stimuli, or rough versus smooth tactual stimulation underfoot. Following this, the animals were trained to perform a successive discrimination in a T-maze, being reinforced for turning left in the presence of one level of brightness and right in the presence of another. Roughness of the flooring was present (though irrelevant) in the transfer task. The group initially trained to brightness showed positive transfer to the second task, whereas no positive transfer was made by the group trained with differential tactile stimulation. Presumably the first task for the brightness pretraining group provided a set for differential responding to the brightness cues that was still present at the time of learning the second task; the differential responses learned by the tactual pretraining group, however, were irrelevant to the transfer task and may even have been expected to produce negative effects.

Other evidence for mediational processes involved in animal learning comes from a study of Grice (1948), who facilitated discrimi-

nation learning under delays of reinforcement by (1) allowing the animal to feed in a goal box of the same color as the reinforced stimulus, or (2) forcing the animal to make characteristically different motor responses while traversing the alley in the presence of the discriminative stimuli. Similarly, Riesen (1940) found that stimulus predifferentiation training facilitated chimpanzees' subsequent discrimination learning under delayed reinforcement. In these experiments, it may be presumed that learning under delay was facilitated when distinctive response-produced stimulation was paired with each of the discriminative stimuli, thus making the stimulus complexes *effectively* more distinctive.

Vicarious trial and error It is interesting to speculate on the possibility that "vicarious trial and error" (VTE, see p. 769) behavior is a visible indicant of mediational processes in operation. As early as 1912, Lashley observed that his rats hesitated and waved their heads back and forth when faced with the choice of one or another discriminative stimulus in a discrimination box. As Lashley again observed (1938), the head waving and alert watchfulness is very apparent in the jumping-stand situation. The behavior is often described as "crouching to jump at one door and then crouching before the other door, before finally jumping"; often such behavior is most marked just before a run of correct responses is noted. This increase in VTE up to the point of solving the discrimination problem was named by Muenzinger (1938), who also noted its decline following attainment of asymptotic performance in animals. White and Plum (1965) have recorded the same trend in children as they oriented their eyes while undergoing visual discrimination learning. A number of experiments with animals (for example, Muenzinger, 1934; Muenzinger & Wood, 1935; Muenzinger & Newcomb, 1936; Muenzinger & Fletcher, 1937; Muenzinger, Bernstone, & Richards, 1938) have shown that shock for incorrect responses increases VTE in a discrimination learning situation, and these writers report that such behavior seems to prolong and improve the animal's reception of the pertinent cues. Contrary to what one might expect, however, Tolman (1939) observed that rats exhibit more VTE in learning a simple white-black discrimination than while learning more difficult grey-black discriminations. This may merely suggest that discrimination problems that afford more "conflict" generate more VTE; an animal in a situation that calls for discrimination between distinctive stimuli should soon learn that reinforcement is differential, whereas an animal in a situation that calls for discrimination between similar stimuli might not learn that reinforcement is differential until much later in training. It is only after that aspect of the learning situation has been appreciated by the subject that head-waving and other eye-orienting skills should appear.

Tolman (1941) pointed out that human subjects in psychophysical experiments tend to evidence VTE from the start, but humans are usually aware at the outset through instructions that there is a solvable problem at hand. Tolman and Minium (1942) conducted an experiment which lends credibility to this interpretation. They started a group of rats on a white-black discrimination that was continued well past the attainment of asymptotic performance. The VTE count was high just prior to solution and then diminished, as is typical. Then the task was made more difficult by substituting light gray for white as the positive stimulus. VTE rose again as the animals made errors in the early stages of the changed problem, then declined. The task was again made more difficult by substituting dark gray as the positive stimulus, and VTE was again in evidence. It would appear that as a solution is approached, less orienting behavior is required and that VTE is most in evidence when conflict is maximal.

Perhaps VTE can be most easily and parsimoniously viewed as an adaptive mechanism designed to enhance proprioceptive and

visual feedback in association with the pertinent discriminative stimuli. This feedback is self-administered through VTE and combines with external physical stimuli to enhance the distinctiveness of the cues to which differential responses must be learned. VTE facilitates, then, the development of a type of acquired distinctiveness of cues.

Concept formation A word should be said of the relationship of mediational processes to concept formation. Acquired equivalence of cues has already been described as involving the learning of a common (or similar) response to two or more discriminable stimuli. This common response produces negative transfer when those stimuli are again encountered. Thus, if a subject learns to say "zim" to two physically different stimuli, such behavior will retard the acquisition of different responses to those stimuli. However, the effect of such pretraining is not always "negative." In fact, this kind of event plays a role in the formation of concepts. In this view, if a child learns that objects as dissimilar as a train, bicycle, and boat are all "vehicles," he is helped to deal with all in terms of their common properties as means of transportation. In such cases, facilitative generalization enables the articulate human to engage in high-level or abstract cognitive processes.

A relatively simple experiment on concept formation was conducted by Long (1940) on children 3 to 6 years old. A box with two small windows was placed before the child. If he pressed on the correct window, he received some candy. Through one window could be seen a rubber ball, through the other a rectangular wooden block. The ball was the

Figure 17.16. Six of the radicals used in Hull's study, with their assigned nonsense names and some characters containing each radical. (Hull, 1920.)

positive stimulus. When the child had learned to choose the ball regularly, he was tested with spherical objects of various sizes, colors, and materials. As expected from a mediational interpretation, which would suppose that the children were taught the concept of sphere or ball, the subjects chose the spherical objects in preference to the angular objects with which they were paired. Moreover, the extended generality of the concept was made manifest when the children tended to pick flat cardboard circles over flat polygons. They also chose the one more nearly circular when two polygons were presented, this effect being most pronounced for the older children in the study.

Other studies of concept learning in adults and children include those of Welch (1938), Welch and Long (1940), Heidbreder (1946), Buss (1950), and Vinacke (1951).

A study by Hull (1920) remains a systematic classic in the area of concept formation. Hull's concepts consisted of Chinese characters; because his subjects were Americans unfamiliar with the Chinese letter system, the use of these stimulus materials assured that the learning of new concepts was truly involved. Nonsense names such as "li," "ta," and "deg" were assigned to various components of larger Chinese characters or compounds, and the subjects tried to discover and to memorize the names of each of these components. Each of the compounds employed by Hull contained one of the 12 selected components, and all of the compounds containing the same component were assigned the same name. The compounds were written on separate cards, and the cards were assembled into packs of 12 so that each pack contained all 12 components (Figure 17.16). Pack No. 1 was exposed serially and, as each character was shown, its name was spoken by the experimenter and repeated by the subject. The subject tried to anticipate (through paired associate learning) the successive items beginning with the second complete presentation of the pack until all the 12 names of the 12 compounds had been learned. Then Pack No. 2 was shown, and the subject was told that the same names were pertinent and that guessing could begin on the first presentation of Pack No. 2. After each guess, the experimenter spoke the correct response, so the subject always knew whether he was correct, and had the benefits of instant correction of his mistakes. The order in which the components appeared, of course, was different from one pack to another. Six packs were learned in this manner and the percent of first-trial "guesses" was shown to increase with each successive pack. It may be presumed that this positive transfer involved the operation of response-produced stimulation, which served to guide the eyes in their search for the "li," "ta," or "deg." Calling attention to pertinent cues of complex discriminative stimuli is apparently a functional property of mediational or conceptual processes. At the end of the experiment, each subject was asked to sketch each of the components that corresponded to each name. In some cases, components that were correctly identified during the experiment could not be correctly sketched. This is a familiar phenomenon in everyday life: objects (or people) may appear similar without our being able to specify exactly how they are similar.

The delayed-reaction procedure Often, a choice must be made at some time after the controlling discriminative stimuli have disappeared. How long can information about stimuli be "held" by the organism during such a period of "stimulus black-out"? We know that sometimes humans do very well at such tasks (you may put away a book and return in a week to retrieve it), but the abilities among other animals vary widely. Systematic study of the question has been carried out with the "delayed reaction" method pioneered by Hunter (1913, 1917). In this kind of experiment, discriminative stimuli are observed by the subject, and then the stimuli disappear for an interval before a discriminative response is permitted. Hunter found that
Figure 17.17. Hunter's delayed-reaction box of the size used for rats. One of the three stimulus lamps was lit, but the rat was detained behind the glass barrier after the lamp went out. After an interval, the barrier went up and the rat could go to any one of the doors. If it entered the door where the lamp had been lit, it was free to run around to the entrance and find food. Rats went to the correct door after delays of less than a few seconds, but only if they maintained their orientation toward that door during the delay.

the proficiency of children in this type of task increases with age (and verbal skill) and also found evidence that animals higher on zoological or evolutionary orderings do better at delayed response tasks.

Two kinds of delayed reaction situation were investigated by Hunter, the two-stage (or indirect) and the one-stage (or direct) method. The two-stage method involves first training the organism in the basic discrimination problem, to which the delayed reaction procedure will later be added. In Hunter's procedure (see Figure 17.17), the subject was confronted with a three-choice discrimination problem which required going from a start box to the one of three doors which was lighted with a cue light. On different trials, the cue light appeared over a different door. Once this discrimination was learned, the delay period was introduced by turning off the cue light while the animal was still in the start box. The start box, however, had a transparent wall facing the doors and cue lights, so the animal could observe the location of the cue light and "note it" prior to his eventual release. The delay was introduced gradually, the light being turned off at first while the animal was on his way to the door, then just as he was released from the start box, then before the release, and with increasing intervals thereafter. The delay was eventually lengthened until the animal could no longer perform correctly on more than one-third of the trials. Most rats in this situation could not "hold" the information provided by the stimulus for more than 4 seconds or so, although occasionally it seemed that an animal could succeed at 10 seconds. (It is difficult to assess the performance of animals from individual trials, for a correct choice would be expected by chance on one-third of the trials.) Hunter noted that animals performed better under the delay situation if they adopted some technique for maintaining their bodily orientation in the direction of the vanished cue, and he noted that dogs run in a comparable chamber could respond correctly after a delay of as long as 5 minutes if they stood, sat, or lay with their bodies or heads pointed in the direction of the cue light.

Raccoons and children were also studied in discrimination chambers adapted to their respective sizes. Children, of course, were able to "hold" the stimulus after-effects the longest of all subjects, responding correctly even in the absence of body-orientation or leg-pointing behavior after 4 minutes or longer. Because older children and adults are capable of verbalizing the location of the correct door ("left," "middle," or "right") and can use these response-produced cues in place of body orientations to guide them at the end of the delay interval, there is almost no limit to the delay intervals such subjects can master.

The one-stage method for testing delayed reactions simply involves the immediate introduction of the delay period without prior discrimination training. In a study with his own 13-month-old daughter, Hunter (1917) seated the child in easy reach of a three-box arc. She watched as a toy was placed in one of the boxes and the lid closed. Her eyes were then closed, or she was picked up and turned around. Finally she was reseated before the boxes and allowed to make her choice. By the end of the study she was able to perform correctly in about 80 percent of the trials after a delay of 15 seconds. By this time she was approximately 16 months of age.

Hunter's commentary in this 1917 report is relevant to our consideration of mediational processes and their effects upon discrimination learning.

> The delayed reaction problem can be solved in at least two ways: (1) by the maintenance of bodily orientation in whole or in part during the interval of delay or by chance recovery of the proper orientation just at the moment of release; and (2) by the use of some intra-organic factor which is *non*observable by the experimenter. . . . The cue used in the second method may or may not be retained in the focus of neural activity during the delay. . . . What one has, then, is a system of processes or cues which "stand for" certain differential responses as a result of association. These cues are susceptible to selective re-arousal and subsequent successful functioning in initiating responses (p. 86).

Following these passages, Hunter goes on to speculate that in articulate organisms the "holding" of the appropriate cues may be through the vocal organs, but he insists that other sites may also be involved, as in kinesthetic stimulation. "Language is ideational in nature. So also are the cues which function in many responses of raccoons, of children, and possibly of dogs. The resulting conception of these cues is that they are kinesthetic sensory ideas" (Hunter, 1917, pp. 86–87). By thus invoking covert vocal and motor mediation, Hunter was one of the earliest learning theorists to elaborate a basic stimulus-response interpretation of complex discrimination learning processes.

Since Hunter's work, other studies have provided additional evidence of mediation during delayed response in human and animal subjects. Spiker (1956) studied 54 preschool children who were divided into two groups. One group initially learned distinctive names for stimuli, while the other was given discrimination training that did not include name learning. The subjects were then given a delayed-reaction test involving the pretraining stimuli. The subjects who had associated names with the discriminative stimuli made more correct choices following delay than the subjects who had not associated names for the stimuli, and this difference was most pronounced for younger subjects. In accordance with the mediation hypothesis, Spiker suggested that having names for the stimuli permits the subject to produce a representation of the absent stimuli during the delay period.

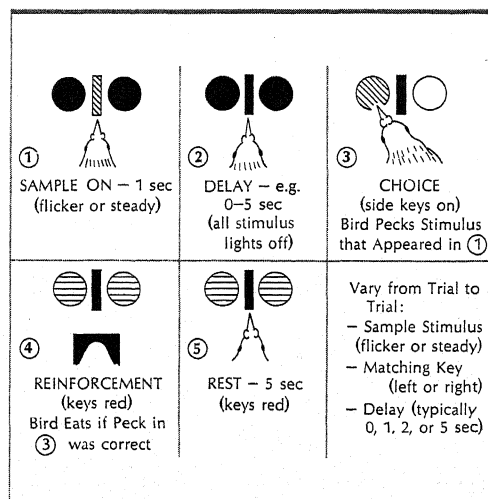
As we have seen, Hunter and others showed how animals might mediate a delay by orientating themselves toward the correct stimulus. Blough (1959) set up a matching task


Figure 17.18. Scheme for delayed matching to sample in pigeons. (After Blough, 1959.)
Figure 17.19. Performance of a bird on the delayed matching task shown in Figure 17.18. The bird cannot bridge the delay by maintaining orientation, as in Figure 17.17. In some cases, symbolic behavior appeared to bridge the delay interval. One instance is shown: when the sample flickered, the bird began to wave its head back and forth, and when the sample was steady, the bird began to peck. When these behaviors continued during the delay interval the bird responded correctly after the delay. Other behaviors that were not as different as head waving and pecking were not as successful in bridging the delay. (After Blough, 1959.)

with pigeons where this was impossible since position was not a critical cue (Figure 17.18). The pigeon had to "remember" whether the center rectangle or "sample" was a flickering or steady light and after a delay peck at the circular key, which might be either right or left, that matched the sample. Two out of four subjects developed mediating behavior that helped them bridge the delay. The most marked example of this behavior is shown in Figure 17.19. When the sample flickered, the bird backed quickly away from the keys and waved its head slowly back and forth during the delay. Following a steady sample, the bird spent the delay pecking rapidly at the top of the rectangular sample. Sometimes, the bird did not maintain its head waving following a flickering sample through a long delay but began, instead, to peck at the sample. When this happened, the bird almost always pecked the wrong key (the steady stimulus, in this case) at the end of the delay. These and other observations reported by Blough suggest that the motion of the bird's head served to mediate the matching performance. Of course, the mediation here was overt, and yet it was "symbolic" in the sense that, like names, but unlike the orientation of animals in Hunter's experiments, the mediating behavior was apparently arbitrary. Blough shows how such mediating behavior might arise from "superstitious" responding (pp. 675, 692) and be maintained because it leads to a high percentage of reinforced trials.

MOTIVATIONAL VARIABLES IN DISCRIMINATION LEARNING

Hunger, anxiety, frustration, and other members of that ill-defined category of variables that we identify as "motivational" can play critical roles in the control of discriminative behavior and in the course of discrimination learning. We have neglected such factors thus far in this chapter, and although they are discussed in detail elsewhere (Chapter 18), we suggest in the present section two examples of research concerning the effects of motivational states on discrimination learning.

Anxiety and stress effects Capitalizing upon the basic Hullian assumption that habit or associative factors (H), on the one hand, and drive or motivational attributes (D) of the organism, on the other, combine multiplicatively to determine response strength, Spence (1956, 1958) and Taylor (1956) deduced that increases in the level of drive should have differential effects depending upon the type of learning task at hand. They reasoned that because drive is presumed to enhance all response tendencies indiscriminately, such enhancement will (1) facilitate discrimination learning when the response to be learned is of higher strength than other competing responses in the habit-hierarchy, and (2) impair learning when the response to be learned is of lower strength than other responses in the hierarchy. In the latter instance, increases in drive will enhance the probabilities of the competing, higher-strength responses, thus

retarding acquisition of the response lower in the hierarchy. Spence and Spence (1966) have reviewed in detail the rationale of these deductions, and data bearing on them, particularly in experiments that use measures derived from the Manifest Anxiety Scale to indicate human drive level.
Figure 17.20. Experiment showing the differential effects of stress on different response tendencies. The "dominant tendency" of children is to press the button below the lighted lamp (see diagram above). In some cases, this was the correct thing to do (dominant tendency correct—DTC); in others, a different button had to be selected (dominant tendency incorrect—DTI). The curves show that stress improved performance of the dominant-tendency-correct task, but made performance worse on the dominant-tendency-incorrect task. (After Castaneda & Lipsitt, 1959.)

Although many of the studies on the interaction between drive level and task difficulty (or amount of intra-task competition) have employed verbal learning materials, some have used learning tasks involving motor discrimination (Castaneda & Palermo, 1955; Castaneda, 1956, 1961; Castaneda, Palermo, & McCandless, 1956; Palermo, 1957; Castaneda & Lipsitt, 1959). These studies used both anxiety measures and stress manipulations as drive variables, with children as subjects. Castaneda and Lipsitt, for example, used an 8-stimulus, 8-response apparatus (see Figure 17.20) in which fifth-grade children had to learn to press the appropriate button when each of the 8 stimulus lights was successively activated. The buttons were lined up below the lights, and for some of the lights the buttons immediately underneath were correct, but for others, the correct button was displaced by one position. Preliminary observations of children's behavior in this situation indicated that without instructions children would tend to press the button below each light; this, then, was the "dominant tendency." The learning situation was so structured that some of the S-R pairings were of the dominant-tendency-correct kind whereas others were dominant-tendency-incorrect. In line with the Spence deductions, it was presumed that drive increases would facilitate learning of the dominant-tendency-correct S-R pairings but would retard learning on the dominant-tendency-incorrect pairs. The drive condition was manipulated through stress instructions; the high-drive subjects were put under a time pressure to respond as quickly as possible, but the low-drive subjects were not so pressured.

As expected (see lower portion, Figure 17.20), the interaction between the type of pair, on the one hand, and drive level, on the other, was obtained. The subjects performed better on the dominant-tendency-correct pairs when under a high-drive condition, but performed more poorly than their counter-

parts with low drive on the dominant-tendency-incorrect pairs. Thus both facilitation and impairment were produced through this within-subjects design in the same subjects at the same time depending upon the type of S-R pair being considered. A companion experiment by Castaneda (1961) replicated the study with higher and lower Manifest Anxiety Scale scorers, rather than stress instructions, and produced the same findings.

The insoluble discrimination problem In all of the discrimination methods thus far considered, the subject may maximize the number of reinforcements received by adopting a consistent mode of behavior in relation to the stimulating circumstances. There exist, however, situations similar to discrimination tasks in which the subject cannot possibly obtain more than the chance number of reinforcements. In a jumping-stand, for instance, the experimenter may give a rat reinforcement half of the time whether it goes to the left, the right, to black, or to white. Such a procedure presents to the animal an insoluble discrimination problem, and such problems sometimes lead to rather unusual, if not bizarre, reactions, at least in some infrahuman organisms.

In extensive studies with insoluble discrimination situations, N. R. F. Maier and his colleagues found that a "frustration-fixation" phenomenon characteristically resulted from subjecting animals to an essentially random schedule of reinforcement that bears no relation to responding (Maier, Glaser, & Klee, 1940; Maier & Klee, 1941, 1945; Maier, 1949; Feldman & Ellen, 1951; Ellen, 1956). The animal's "fixation" reaction under such conditions usually took the form of so-called "perseverative responding" to a position cue: it might, for example, jump repeatedly to the left. An interesting outcome was that even when the stimulus problem changed such that the animal could now receive reinforcement all of the time by responding to one of the cues (such as black or white), the fixation persisted. The animal did not readjust his behavior to the now-consistent reinforcement consequences, even if administered hundreds of trials on which he was positively reinforced for going to black and punished for going to white. Not only did the fixation persist, but so did the interesting appearance of the animal that was subjected to the frustration condition. Rats that have been treated in this way may become like a ball of fur in one's hand; these rats behave very oddly even by rat standards, failing to show the usual kinds of righting reflexes during a fall, and showing great flaccidity in general. Their condition, in fact, has been likened to that of the typical catatonic schizophrenic human, and Maier has been tempted (1949) to draw the parallel between the conditions producing this characteristic in animals and the likely conditions producing catatonia in humans. The parallel with human psychopathology is made even more striking, moreover, by the demonstration (Maier & Klee, 1945; Ellen, 1956) that guidance of the fixated animals to the correct stimulus is effective in breaking up the animal's discrimination fixation and restoring muscular tone.

Whereas Maier tends to regard the behavior of animals in these frustration situations as representing the consequences of "behavior without a goal," others (for example, Farber, 1948) have insisted that such behavior is best understood in reinforcement terms as a type of avoidance reaction. According to this latter view, the animal is in effect reinforced for *not* paying attention to the "discriminative" stimuli (which are not discriminative at all); they must jump in this situation because typically an air-blast or an electric current is applied on the jump-stand if a certain latency of response is exceeded. Thus the animals make the "adaptive" response of jumping, even if abortively. For another treatment of the manner in which learning principles may be applied to account for seemingly abnormal behavior in animals and humans, see Lundin (1961).

Although the studies reviewed in this section are fairly representative of the ways in

which standard discrimination learning situations can be utilized in the study of motivational states and individual differences, laboratory techniques have not yet been used as extensively as they might be for the study of behavioral abnormalities. Techniques of the learning laboratory—careful specification of stimulating conditions, development of reliable procedures to assess responses, study of the acquisition of new behavior, and search for ways in which many factors interact lawfully to produce behavioral outcomes—will eventually be used more widely to illuminate the genesis of anomalous behavior patterns.

Alexander K. Bartoshuk

MOTIVATION*

18

INTRODUCTION

For approximately the last fifty years of experimental psychology, most motivational formulations may be viewed largely as variations and elaborations on a theme by Woodworth (1918). For the sake of brevity, we will start with this reference point;[1] then we will turn to a consideration of related contemporary motivational theories, with emphasis on their empirical bases and implications. We will not be primarily concerned with representing the great diversity of views on motivation. Instead, we will examine a frequently postulated and emphasized factor: nondirective generalized drive, which energizes behavior without guiding it; and we will discuss some related psychophysiological conceptualizations of activation or arousal as a general energizer without steering properties. We will refer briefly to the hypotheses that instrumental responses are reinforced by drive reduction and punished by drive onset; these are important aspects of drive theory (see Chapters 15 and 16 for more extensive treatments of positive reinforcement, and of negative reinforcement and punishment). In addition, generalized drive theory will provide us with a frame of reference within which we will consider

* Preparation of this chapter was supported in part by a United States Public Health Service Research Scientist Development Award, Type II (5-KO2-MH21837), from the National Institute of Mental Health.

[1] For earlier related formulations of psychological forces or "activators," mostly implicit, see Boring (1950), Woodworth (1958), and Bolles (1967).

several theoretical alternatives to generalized drive theory for interpreting or explaining particular results or problems.

Mechanism (S-R) and Drive

In an important work on the history of experimental psychology, Boring (1950, pp. 722-723) portrays the essentials of Woodworth's (1918) "Dynamic Psychology" as follows:

> Woodworth in 1918 was emphasizing the importance of *mechanism* and *drive,* trying to show that these two concepts can together account for all human activity. The mechanism of an act is the linkage. . . . stimulus-and-response relations (S-R) are mechanisms which can be described. Outside the mechanism, however, lie sources of energy ready to activate this or that mechanism . . . They are drives. If an animal is thirsty, the go-to-water mechanism is activated by the thirst drive; if hungry, the hunger drive activates the get-food mechanism.[2]

How the topic of motivation was delimited by Woodworth and Schlosberg (1954) may be gathered from the following introduction to the 1954 chapter:

> It is recognized in everyday life that a person's performance on a given occasion does not always measure up to his ability. He does not run as fast or shoot as accurately or speak as convincingly as he has on other occasions. He is perhaps not highly motivated, or he may be overmotivated and so eager to succeed as to lose control of his resources of energy and skill. Both ability and motivation are factors in performance, and if either of them is entirely lacking, the performance does not occur. Ability is like a machine which cannot do its work unless power is applied.

Figure 18.1. Effects of shifts in deprivation time on the mean log time taken to run a 10-unit T-maze for water by water-deprived rats. Group 22–2 (●-- ●) ran trials 1–10 under 22-hr deprivation and trials 11–15 under 2-hr deprivation; Group 2–22 (O--O) ran trials 1–10 under 2- and 11–15 under 22-hr deprivation. The arrow indicates the initial trial after the deprivation times were shifted. Groups 2–2 (●—●) and 22–22 (O—O) were controls run under the same deprivation times throughout trials 1–15. Note the increase in running time immediately after the 22–2 shift, and that within 2 trials Group 2–22 ran almost as quickly as Group 22–22. (Hillman, Hunter, & Kimble, 1953)

These ideas may be viewed as preliminary attempts to identify the broad categories of variables ("mechanism" and "motivation") that together determine performance under conditions that need to be specified.[3]

Illustrations of Motivational Effects

Several effects of an alleged motivational variable (water deprivation) on performance are illustrated in Figure 18.1. With either 2 or

[2] Woodworth's (1938) *Experimental Psychology* did not have a chapter on motivation; the index did not include the term "Drive," and only five pages are cited under "Motivation." In his Preface, Woodworth explains the omission of the topic of motivation as follows: "All of these branches are of great interest to me, personally, but the scope of the book is fully broad enough when confined as it is to the usual content of a course in experimental psychology, in which the students and subjects are young human adults. I should have liked to include chapters on work and motivation, but must content myself with a reference to Robinson's comprehensive chapter on the 'Work of the Integrated Organism' in Murchison's *Handbook,* and to such treatments of motivation as are given by Troland, Young and Gordon Allport." *Experimental Psychology* by Woodworth and Schlosberg (1954) does have a chapter on motivation in learning and performance; the index includes thirty-one items under "Motivation" and thirty items under "Drive." Woodworth's (1958) updated version of *Dynamic Psychology* became *Dynamics of Behavior.* It reveals his enduring interest in motivation and drive in relation to contemporary research.

[3] The lack of agreement among psychologists on the definition of a concept of motivation, and the diversity of topics labeled as motivation may be gathered from the articles by Mowrer (1952), Cofer (1959), Irwin (1961), O'Kelly (1963), Brown and Farber (1968), and Campbell and Misanin (1969) in the *Annual Review of Psychology,* and from the annual series of articles in the Nebraska symposium on motivation from 1953 on.

22 hr of water deprivation, we see that on a 10-unit elevated T-maze rats ran faster for water at the higher deprivation. When subgroups were shifted from 2 to 22 or from 22 to 2 hr of water deprivation, performance shifted appropriately: 2–22 subjects ran faster within two trials after the shift, and 22–2 subjects ran more slowly immediately after the shift than they had on the preceding trial. The important assumption is made that this rapid shift in performance, perhaps especially the slowing down, does not appear to be a learning phenomenon (although possible associative explanations, such as generalization decrement, will be considered later). These rapid performance shifts illustrate the type of performance changes which would be predictable if performance was a multiplicative function of learning and drive.[4] More simply, Figure 18.1 illustrates performance changes attributable to a motivational variable (in this case, shifts in hours of water deprivation as a source of drive). We should also emphasize that as is often the case, the number of errors was *not* related to degree of deprivation throughout the 15 trials; this illustrates the important fact that the observed effects of motivational variables on behavior can vary markedly with the particular response measures used.

Shifts in magnitude of both positive and negative reinforcing stimuli may produce changes in performance somewhat similar to those observed with deprivation shifts: in other words, it seems reasonable to think of such shifts having motivational effects. Thus, besides deprivation as a source of drive, additional "energization" or facilitation of performance may arise from the reinforcers as a source of incentive motivation. An early example was provided by Blodgett (1929), who demonstrated that food-deprived rats run in a maze without food showed marked improvement in speed and accuracy immediately after the introduction of food in the goal box. Rapid shifts in asymptotic starting latencies were found by Zeaman (1949) when large and small amounts of food were interchanged (see p. 631ff.). These aspects of Zearman's data confirm the findings of Crespi (1942, 1944), who emphasized their motivational significance. Such rapid performance shifts with reinforcement shifts illustrates that so-called "motivational effects" may depend in part at least on incentive motivation (based on learned associative mechanisms), and to that extent motivational effects cannot be uniquely attributed to deprivation conditions as sources of drive. Hence "motivation" is frequently used as a generic term which subsumes drive and incentive motivation.

[4]The use of an experiment, such as that described here, to illustrate a particular theoretical formulation does not necessarily mean that all available data are unequivocal with regard to this interpretation. For opposing views see Webb (1955) and Bolles (1958, 1967).

CRITERIA FOR MOTIVATIONAL VARIABLES

Concise, valuable discussions of the criteria for identification of motivators defined as manipulable empirical motivational variables (for example, food deprivation, electric shock) are provided in Brown (1961) and in Brown and Farber (1968). Briefly, three possible criteria appear to be most often invoked: First, a motivational variable should energize many different responses under standard stimulus conditions appropriate for each response tested; second, a motivational variable's offset should reinforce immediately preceding responses; third, its onset should punish immediately preceding responses.

For example, electrical shock functions as an energizer, its onset as a punisher, and its offset as a reinforcer. Because electrical shock appears to meet all three criteria, it qualifies as a motivational variable. However, for other motivational variables, the empirical correlations among these criteria are not known for a wide variety of situations, and therefore Brown and Farber (1968, p. 102) note that ". . . it is uncertain whether more than one criterion must be met." The question of unknown correlations among the three criteria is mentioned here to make explicit the fact that fulfillment

of one criterion does not ensure fulfillment of the others.

This chapter is concerned primarily with the first criterion and the usefulness of the concept of drive as a general energizer. We refer to the other two criteria here only to a limited extent in the context of drive theory because the relevant topics of reinforcement and punishment are discussed in two other chapters.

Energizer

Probably the most widely accepted criterion for identification of a motivational variable is that it should facilitate or energize behavioral response tendencies. Earlier drive theories often implied selective facilitation (for example, food deprivation activates the get-food mechanism). Recently, facilitation of a wide variety of response tendencies has been favored (Brown, 1961, p. 41). Thus for some theories an essential property of drive originating from food deprivation is that it energize or facilitate other mechanisms besides those regulating eating or reinforced with food (Hebb, 1955; Brown, 1961). Although the S-R associative mechanism can result in only one dominant response in a particular situation, the idea of a generalized energizer is still testable because, in principle, any one of a wide variety of responses can be made dominant, provided the stimulus conditions are varied appropriately. To illustrate, R_1 can be made dominant in one situation, R_2 in another, and so on; each of these different responses should be demonstrably energized by any motivator as a source of generalized drive, provided the test response is the dominant response in the test situation.

Some observations on spinal reflexes are at least suggestive of a general energizer such as drive (and/or arousal as discussed in a later section). Sherrington noted that (1900, p. 845, cited by Brobeck, 1960, p. 1203);

> As a broad rule, spinal reflexes are more easily elicited when a well-nourished animal is hungry and expecting food, and less readily when it has just heavily fed.

It is interesting that Sherrington's wording includes reference to factors now considered as drive and incentive motivation. Experimentally produced thirst results in facilitation of evoked responses from spinal ventral horn cells (Wayner, 1964). Both of these observations are at least suggestive that the procedures alleged to produce drive tend to facilitate skeletal responses in general.

This view receives some support from the finding that startle responses to the sound of a pistol shot were reliably greater in rats food-deprived for 46 hr (high drive) than for 1 hr (low drive); but the initial effects of food deprivation on startle were extremely slight relative to the tremendous enhancement of startle by fear (Meryman, 1952; cited by Brown, 1961, pp. 152–154). These quantitative data on the effects of food deprivation on startle suggest that any generalized energizing effect of food deprivation per se is small.

The example with startle as a test response illustrates attempts to translate into experimental terms the proposition that motivational variables act as a general energizer; the assumption is made that startle is not relevant to "get-food" behavioral patterns and consummatory mechanisms, and therefore startle would not be enhanced by food deprivation if the latter only energized specific mechanisms relevant to the deprivation. On the other hand, if startle were enhanced by food deprivation (as indeed seems to be the case), it might be seen as evidence in favor of the general energizing theory of drive.

Reinforcement by Motivational Variable Offset

In escape from electrical shock, escape turns off the alleged motivational variable (electrical shock) and the responses leading to escape are supposedly reinforced by the shock offset. Now, if escape becomes more precise, more rapid, and in other ways shows evidence of learning, we might say that electrical shock is a motivational variable (that is, an empirical one) because it has met one of the criteria. Acceptance of this paragraph so

far does not commit one to accept theoretical concepts of generalized drive or multiple drives, nor that drive reduction is essential for reinforcement.

Hours of food deprivation can be considered as a manipulable empirical variable in the sense that duration of the privation can be systematically varied, but in the present context we should note that the precise empirical assessment of this variable's offset poses difficulties. Earlier thinking involved the view that there are primary biological needs which must be met for survival, that these need states are sources of drive, and that reduction of a biological need is accompanied by drive reduction which reinforces the instrumental activity leading up to need and drive reduction. The marked reduction in the efficacy of reinforcers when delayed only a few seconds (see delay of reinforcement section, pp. 677–689) makes it clear that reinforcement must be occurring minutes before the ingested food could be transformed into usable forms and transported to bodily tissues where it could reduce need. Ingestion of water seems to reverse deprivation conditions more rapidly, but this delay is still very long by delay-of-reinforcement standards. Clearly, the reinforcing event precedes need reduction and the offset of this alleged motivational variable apparently occurs at the wrong time to be the immediate cause of reinforcement.

Perhaps food deprivation should be empirically defined as a period of noneating which is terminated by eating food. However, available data show that eating nonnutritive materials can also reinforce responses. For example experiments with nonnutritive saccharin have demonstrated that it is ingested avidly by most animals and that it is an excellent positive reinforcer although it does not reduce caloric needs (see pp. 627–630). Hence, it has been suggested (for example, Sheffield, Roby, & Campbell, 1954) that reinforcement may be primarily due to the occurrence of consummatory activity.

However, even consummatory activity is not essential for food to be a reinforcer for a food-deprived subject. Experimental data have shown convincingly that instrumental activity can be reinforced with food given through a stomach fistula (Miller & Kessen, 1952) or through a nasopharyngeal gastric tube (for example, Epstein & Teitelbaum, 1962; Borer, 1968). However, nonnutritive saccharin (which does not, of course, directly reduce caloric needs) does not reinforce behavior when it is given via a stomach fistula (Miller, 1955).These results seem to indicate that need-reduction can be a sufficient (though not a necessary) condition for reinforcement, even in the absence of consummatory activity.

It should not be concluded that just because saccharin passes through the body without chemical change it is therefore physiologically inert. Ingesting saccharin has sometimes increased and sometimes decreased blood sugar levels, and even rinsing the mouth with saccharin and other substances may produce such changes (Jorgensen, 1950; Nicolaides, 1969). Some of these changes (called "anticipatory reflexes" by Nicolaides) occur within a minute of oral stimulation, but even such intervals are long by delay-of-reinforcement standards. Results such as these provide some support for the hypothesis that saccharin may interact with need-reducing mechanisms in as yet undetermined ways (see also Smith & Capretta, 1956; Valenstein & Weber, 1965).

Still another type of experiment used to support the argument that reinforcement can occur without drive reduction was performed by Sheffield, Wulff, and Backer (1951). Male rats were tested to determine whether running and hurdle-climbing could be reinforced by copulation with a receptive female which was interrupted before ejaculation. (The male rat dismounts after each copulation, and a series of about a dozen mountings occur before ejaculation, so removal of the male after the second copulatory response ensured that copulation occurred without ejaculation). Significant improvement in instru-

mental response speeds supported the conclusion that instrumental responses were reinforced by copulatory activity, even when copulation had never been followed by an orgasm, and thus presumably without any reduction in drive of a sexual origin. Kagan (1955) reports that sexual behavior allowed to continue until ejaculation was a better reinforcer for rats than coital behavior without ejaculation; this differential reinforcing efficacy was apparently primarily due to deteriorating performance of males not allowed to ejaculate. Whalen (1961) has shown that intromission without ejaculation is self-maintaining and reinforces T-maze learning when no other type of sexual activity is allowed. He suggests that complex effects resulting from intromission on some trials and mounting without intromission on other trials (such as mounting a vaginally closed, nonreceptive female) may be involved in the failure of intromission without ejaculation to be self-maintaining in Kagan's study.

Research in this area has been hampered by lack of techniques for the quantitative assessment of the current drive level. Interrelated with this problem is the question of how convincing the evidence is that drive reduction is essential for reinforcement. Probably the predominant current view is to reject a "strong" version of the drive-reduction hypothesis, and accept it in a weak form such as: drive reduction may be a sufficient condition for reinforcement, but it is not an essential one. Of course, even if this weak form of the hypothesis is accepted, we can still use the presence of a reinforcing effect as one of the criteria of a motivational variable.

Punishment by Motivational Variable Onset

A third criterion for the identification of a motivational variable is that its onset punishes preceding responses. For example, an instrumental response followed by onset of electrical shock then has a lowered probability of recurrence. This criterion works best when applied to the presentation of external stimuli such as electrical shock to the feet, or stimuli which elicit conditioned fear (Brown & Farber, 1968) or the "alarm reaction" (Roberts, 1958a, b, 1962). (The topic of punishment is discussed in greater length in Chapter 16.)

Application of this criterion to deprivations has been difficult because until recently it was not feasible to have an instrumental response followed immediately by a sufficiently rapid onset of hunger or thirst. However, the use of stimulating electrodes chronically implanted in the brain may help to solve some of these problems. For example, Margules & Olds (1962) found that electrical stimulation of the lateral hypothalamus (the so-called "feeding area") caused stimulus-bound eating in 28 out of 46 rats tested. That is, eating began within two seconds of stimulus onset, continued throughout stimulation, and ceased with stimulus offset. Such effects are sometimes interpreted as evidence that the electrical stimulation of the lateral hypothalamus was suddenly turning on hunger, which was reflected in the consummatory activity of eating and the organized searching for food (see Miller, 1960).

If this were the case, our third criterion would predict that immediately preceding instrumental responses would be punished. Instead, they are positively reinforced. For example, bar-pressing increases (Hoebel & Teitelbaum, 1962; Margules & Olds, 1962) and T-mazes are run with increasing speed and accuracy (Miller, 1960; Mendelson & Chorover, 1965) when the same electrical stimulation is turned on immediately following the occurrence of the response.

These results would seem to suggest that forms of stimulation that do not elicit strong withdrawal reactions can be positively reinforcing at the same time that they are drive-inducing (see pp. 657, 695), and that our third criterion may thus be relevant only to stimuli that are aversive in nature.

DEFINING CONDITIONS OF SOURCES OF DRIVE (vs DRIVES)

In a discussion of drive as a motivational concept, the requirements include *both* an operational definition of an alleged source of

drive that can be manipulated as an independent variable (such as hours of food deprivation) and appropriate tests to assess whether any of the criteria for the identification of a motivational variable have been met (energizing, reinforcing, punishing). Examples may make this clearer. Air deprivation for rats under water acts as a source of drive (Broadhurst, 1957). Speed of underwater swimming was an increasing monotonic function of duration of air deprivation up to about 20 seconds. Following air deprivation, access to air successfully reinforced the acquisition of a brightness discrimination. In this case, seconds of air deprivation while underwater provides an operational definition of a source of drive; and two criteria for identifying a motivational variable were met: swimming speeds increased with increases in deprivation times and termination of air deprivation reinforced a discriminative escape response. However, mere reduction of the oxygen concentration of air without interfering with breathing apparently does not act as a source of drive: responses are not energized, nor are any instrumental responses reinforced. For example, airmen have lost consciousness when flying at high altitudes even though they could increase their oxygen concentration, either by turning on a supply line or by selecting a lower altitude. There apparently is no physiological mechanism to monitor the oxygen supply directly and to instigate adaptive, nonreflexive behavior. Thus although one can operationally define a technique of oxygen deprivation without interfering with breathing, this does not act as a source of drive.

On this point Brown (1961, pp. 44–47) emphasizes an important distinction between merely operational definitions and significant definitions of drive. A significant definition of a source of drive is essentially an operational definition that works (meets at least one of the criteria for identifying a motivational variable). In other words, identifying a significant source of drive requires both a formal operational definition concerning the manipulation of an empirical variable, plus an empirical test to see if at least one criterion is empirically fulfilled. This means that the identification of a significant source of drive is at best probabilistic and not a logical certainty based on a formal definition.

When discussing significant sources of drive, needs and drive must be distinguished. In some cases, such as food deprivation, one might expect the growing need for calories and the increasing drive level to follow parallel functions. However, even here, a growing physiological need for particular vitamins or minerals can fail to act as an energizer. Failure of oxygen deficits to act as energizers was mentioned at the start of this section. Similarly, carbon monoxide is odorless and poisonous; one can say there is a physiological need to avoid it, but the breathing of air containing such carbon monoxide does not energize responses. On the other hand, clearly aversive intensities of electrical shock are very effective in producing what appears to be a heightened drive state, even though these intensities of shock do not cause any gross peripheral tissue damage, and consequently there is no great and immediate physiological need to avoid such shock to prevent tissue damage. In summary, a one-to-one relation between physiological need and drive does not always occur, and it is not required by contemporary drive theory. It follows as well that the detection or measurement of physiological need in itself does not necessarily provide an index of drive level.

We will now discuss sources of drive under the headings of primary (unlearned), secondary (learned), and response-defined level of drive (where either the source is unknown or where drive level is suspected to have changed although the antecedent deprivation has not changed).

Primary (unlearned) Sources of Drive

Whether spoken of as primary drives or primary sources of drive, lists of primary motivators typically include hunger, thirst, sex, aversive stimuli, perhaps maternal drive, and, recently, something variously called boredom, curiosity, or exploratory drive. No

general agreement exists about the length of the list, except that the need for parsimony dictates that the list be kept relatively short. Inclusion in the class of primary motivators rests on the assumption that they are present in normally raised animals and do not require the special procedures used to establish alleged secondary or acquired sources of motivation.

Antecedent conditions It is customary to consider hunger and thirst as being operationally defined in terms of antecedent conditions (for example, hours of food or water deprivation, respectively). Sometimes, however, food or water deprivation is used to produce a body-weight deficit, and the latter is used as the operationally defined motivational variable. Our earlier discussion of significant definitions of motivational variables emphasized that they only included those variables which met at least one of the empirical criteria for identification of motivational variables. In other words, significant motivational variables as a class are defined by their behavioral consequences as well as their antecedent conditions. Sometimes the behavioral consequences are even emphasized, as in Miller's use of behavioral responses to "measure" hunger, and to argue for drive reduction by saccharin in the absence of need reduction (1957). A response definition or measure of hunger is sometimes implied in studies purporting to show that experience with food-deprivation schedules can override the effects of food deficit per se (see section below on deprivation effects on consummatory activity). Sexual and maternal motivational variables are less clearly anchored on the antecedent side, and in their assessment more weight is given to response measures. Presentation of strong electrical shock to external bodily parts meets the criteria for a significant motivational variable, and has provided a basis for suggesting that at least some significant motivational variables are due to intense stimuli. Attempts have been made to relate curiosity and exploratory behavior to antecedent conditions of stimulation or perceptual deprivation and/or stimulus satiation (boredom); here too, response measures play an important role in current research devoted to identifying significant definitions of antecedent conditions as motivational variables.

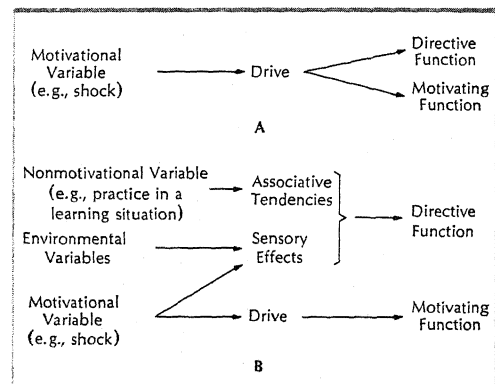
Discrimination of deprivation states It is important to note that rats can discriminate between hunger and thirst, and between different degrees of hunger. First, let us survey some of the data, and then consider four possible theoretical interpretations. Hull (1933) used a maze with two different routes that led to a common goal box in which either food or water was placed. Rats eventually learned after many trials to take the path that provided access to food when food-deprived, and the other path when water-deprived. This


Figure 18.2. Part A illustrates the possibility that an empirical motivational variable instigates a hypothetical drive with both energizing and directive functions. This involves the assumption of multiple drives, such as hunger, thirst, and sex. Other, nonmotivational variables have directive functions, which theoretically could act in conjunction with multiple drives *or* with the general drive illustrated in Part B. Motivational variables, in Part B, are a source of general drive and also have sensory effects with directive functions. The two theoretical formulations of drive depicted in Parts A and B were treated as being mutually exclusive in Brown (1961). (Redrawn from Brown, 1961.)

selection of path in accordance with the current deprivation state was confirmed by Leeper (1935) with fewer acquisition trials by the use of separate goal boxes. More recent experiments (for example, Amsel, 1949; Manning, 1956) support earlier data and strengthen the case for discriminations between hunger and thirst based on some aspect of deprivation and its consequences other than merely generalized drive intensity; some associative mechanisms seem to be required to explain such results. Thus food and water deprivation might each be assumed to have both motivational and directive functions. This is probably true for any motivational variable. We will consider four principal ways to incorporate these two functions into theory.

Figure 18.2, based on Brown (1961, pp. 58–59), illustrates two major alternatives for drive theorists. In Figure 18.2A, the motivational variable instigates a drive with both directive and motivating functions; the directive function presumably would vary according to the motivational variable involved, and in this case it may be meaningful to speak of various drives (such as hunger, thirst, and sex drives). In Figure 18.2B the motivational variable, as a source of drive, contributes to a unitary general drive that is capable of energizing all response tendencies; in addition, the motivational variable (such as electrical shock) has sensory effects that can become associated with response tendencies (be part of the S-R mechanism). These sensory effects of motivational variables have been called drive stimuli by Hull (1943). According to Brown (1961), the terminology "drive stimuli" may have the misleading implication that they have a drive function (they energize response tendencies). Instead, Brown proposes that these sensory effects be called motivation-variable stimuli (S_{MV}s); such terminology may serve to indicate more clearly the purely directive function attributed to them. In this formulation, illustrated in Figure 18.2B, drive energizes but does not direct behavior. The assumption that motivational variables have sensory effects provides a theoretical basis for the experimental data which show rats can discriminate between food and water deprivation. For this formulation, the same procedure (such as food deprivation) can manipulate both drive (D) and motivation-variable stimuli (S_{MV}s). In the absence of clear empirical indices of D and S_{MV}s, practical problems may arise where it may be difficult to assess empirically how much of a behavioral effect is due to D, the general energizer, and how much is due to the cue properties of S_{MV}s and the associative mechanisms noted next.

A third possibility for dealing with the alleged motivational and directive functions of deprivation procedures is to attempt to account for all of the effects of motivational variables in terms of stimulus elements (Estes, 1958). Drive stimuli are treated as any other stimuli capable of becoming associated with responses. It is assumed that as deprivation time increases, the probabilities of occurrence of deprivation cues increase and those of satiation cues decrease. These two sources of cues provide a basis for discriminating among deprivation states. How successful this approach will be in accounting for motivational phenomena is not yet known.

A fourth possibility for dealing with these problems is to invoke the directive consequences of the stimuli arising from the hypothesized fractional anticipatory goal responses, that is, the r_g–s_g mechanisms (Spence, 1951; Logan & Wagner, 1965; Bolles, 1967). When a subject is water deprived but satiated on food, the fractional anticipatory goal response related to eating (r_e) should be reduced, but not the fractional anticipatory goal response related to drinking (r_d), and hence the directive consequences of r_d would contribute cues leading to the place where water previously has been encountered. If it can be shown that this approach adequately accounts for the data on discrimination of deprivation conditions, then there would be no need to postulate deprivation stimuli with cue properties. In fact, Bolles (1967) has suggested that perhaps it is not essential to postulate either

a general energizer called drive *or* deprivation stimuli, and that (p. 367) "Whatever the status of r_g, incentive theories of motivation offer a clear alternative to drive theories."

Drive level as a function of significant motivational-variable parameters In the consideration of food deprivation as a source of drive, it has sometimes been assumed that drive level increases monotonically as a function of the number of hours of food deprivation (see Hull, 1952, pp. 6–7). It has also appeared reasonable to postulate inanition (general physical weakness), and although there were few empirical studies of inanition per se, such enfeeblement has been assumed to increase monotonically as an exponential function of deprivation time. When D was corrected for inanition, the resulting effective drive ($\bar{D}$) was an inverted-U function of deprivation time (for example, Yamaguchi, 1951). In this context, the dominant response tendency should be energized to the extent of $\bar{D}$, and this should be apparent in one or more performance attributes (such as likelihood of occurrence, speed, number of responses, vigor). Therefore, other things being equal, some characteristics of the dominant response should keep increasing as a function of hours of food deprivation, until under sufficiently extreme conditions inanition significantly reduces $\bar{D}$. Similarly, with water deprivation as a source of drive, $\bar{D}$ should be a rising monotonic function of deprivation time until inanition becomes severe enough at extreme deprivations to lower $\bar{D}$.

Among other so-called primary sources of drive, a major one consists of the presentation of strong external stimulation, such as electrical shock. Here drive is assumed to increase monotonically[5] as a function of shock intensity.

Generalized drive theorists assume that drive from these various defining conditions is additive; the various sources contribute, perhaps by simple summation,[6] to a general drive factor (D). Regardless of the sources involved, D supposedly energizes all response tendencies. Actual behavior, therefore, will depend on the S-R mechanism; what the subject does will depend on which response is the dominant one in that particular situation.

[5]Hull (1952) did not explicitly suggest that the subject was generally weakened when electrical shock was used as a source of drive.

Secondary (Learned) Sources of Drive

The basic question here is whether it is possible to take stimulus conditions that normally do not act as sources of drive and, by appropriate procedures, transfer them into learned sources of drive.

Acquired sources of drive derived from strong aversive stimuli A representative experimental paradigm is provided by Miller's (1948, 1951) study of neutral stimuli acquiring fear-arousing properties as a result of being associated with electrical shock (see pp. 717–718). Rats were shocked in a white compartment and allowed to escape into a black compartment. Subsequently, 13 of 25 animals acquired new responses when these were necessary in order to leave the white compartment, even though no further shock was given after the initial experience. These data are consistent with the conclusion that the initially neutral white compartment became a source of drive which energized responses, as a result of the stimuli of the white compartment having been paired with shock. It is frequently assumed that the white compartment now is a conditioned stimulus (CS) which causes a conditioned response of fear.

[6]Food and water deprivations are not independent; water-deprived rats eat less food and food-deprived rats drink less water (see the section on consummatory activities). Attempts have been made to bypass the difficulty due to interaction between hunger and thirst by depriving subjects of either food or water, and then presenting them with other sources of drive, such as electrical shock. These studies on the summation of drive are reviewed in Bolles (1967). How incentive motivation (K), as an alleged general energizer, combines with generalized drive (D) is considered in our section on incentive motivation as a learned source of drive.

Moreover, this point of view predicts that escape from the white compartment (and the fear-arousing stimuli) into the black compartment should be reinforced by motivational-variable offset (that is, termination of the white-compartment cues); and indeed new instrumental responses were learned, apparently on the basis of this reinforcement.

An extensively held view is shared by Brown and Farber (1968, p. 108) when they conclude that: ". . . there is little doubt that the termination of a fear-arousing CS functions as a reinforcer for a wide variety of responses whose occurrence antedates such reactions . . ." and they cite key experimental studies which seem to support their point.

Recently, however, Allison, Larson, and Jensen (1967) have warned against possible misleading and oversimplified interpretations of Miller's results. First, they found in their own experiment that fear conditioning initially depressed speed of escape from one into another compartment in a shuttlebox, relative to nonshocked controls, thus confounding any reinforcement interpretation of the subsequent improvement in performance for experimental subjects escaping a white CS into a black compartment. Moreover, nonshocked controls showed a reliable preference for black over white compartments, both in terms of initial choice and time spent within compartments, so that experimental subjects with a black CS did not show reliable performance improvement for escaping the black CS into the white compartment.

With regard to Miller's (1948) and other studies on avoidance, Bolles (1967) questions whether a really "new" response has been acquired. He argues that on the basis of available data (p. 408) ". . . there seems to be room for considerable doubt whether the rat can learn any arbitrary response in an avoidance situation." Bolles apparently is not only questioning a current view, expressed for example by Brown and Farber (1968), that "a wide variety of responses" can be acquired as avoidance responses; he also suggests (p. 409) that the fear-arousing CS ". . . may merely elicit species specific defense reactions."

In a frequently cited study, Brown, Kalish, and Farber (1951) demonstrated with rats that after a CS had been paired with electrical shock to the feet, startle responses to a sudden intense auditory stimulus (a pistol shot) were enhanced relative to controls for whom the CS had not been paired with shock. This finding is consistent with the view that conditioned fear elicited by the CS acted as a source of generalized drive which energized the indicant or test response, startle. Recently, however, Kurtz and Siegel (1966) found that the amplitudes of startle responses were enhanced (relative to control groups for pseudoconditioning) only by a compound-stimulus CS paired with electrical shock to the rat's feet, but not by the same compound stimulus when it had been paired as a CS with shock to the rat's back. They suggested that foot shock elicited a postural adjustment (crouching) which reduced the severity of the shock. In the presence of the CS for foot shock, on test trials without shock, the rats maintained a crouching posture which apparently heightened startle responses. The crouching posture was not maintained in the presence of the same compound stimulus when it had been paired with back shock, nor in the presence of the same compound stimulus when it had not been paired with shock in the two control groups for pseudoconditioning.

> In seemingly good correspondence with the postural data, startle responses tended to be about equal in the back-shock experimental group and in the back-shock and foot-shock control groups for pseudoconditioning, but about 50 percent larger in the foot-shock experimental group. Kurtz and Siegel granted the possibility that back shock might have produced postural adjustments which tended to reduce the amplitude of startle responses (and presumably that the conditioned postural response might negate the energizing increment due to fear as a source of drive). They noted, however, that acceptance of this possibility serves to underscore the important influence of posture on the magnitude of startle responses, and to question the generality of the "energization" reported by

a general energizer called drive *or* deprivation stimuli, and that (p. 367) "Whatever the status of r_g, incentive theories of motivation offer a clear alternative to drive theories."

Drive level as a function of significant motivational-variable parameters In the consideration of food deprivation as a source of drive, it has sometimes been assumed that drive level increases monotonically as a function of the number of hours of food deprivation (see Hull, 1952, pp. 6–7). It has also appeared reasonable to postulate inanition (general physical weakness), and although there were few empirical studies of inanition per se, such enfeeblement has been assumed to increase monotonically as an exponential function of deprivation time. When D was corrected for inanition, the resulting effective drive ($\bar{D}$) was an inverted-U function of deprivation time (for example, Yamaguchi, 1951). In this context, the dominant response tendency should be energized to the extent of $\bar{D}$, and this should be apparent in one or more performance attributes (such as likelihood of occurrence, speed, number of responses, vigor). Therefore, other things being equal, some characteristics of the dominant response should keep increasing as a function of hours of food deprivation, until under sufficiently extreme conditions inanition significantly reduces $\bar{D}$. Similarly, with water deprivation as a source of drive, $\bar{D}$ should be a rising monotonic function of deprivation time until inanition becomes severe enough at extreme deprivations to lower $\bar{D}$.

Among other so-called primary sources of drive, a major one consists of the presentation of strong external stimulation, such as electrical shock. Here drive is assumed to increase monotonically[5] as a function of shock intensity.

Generalized drive theorists assume that drive from these various defining conditions is additive; the various sources contribute, perhaps by simple summation,[6] to a general drive factor (D). Regardless of the sources involved, D supposedly energizes all response tendencies. Actual behavior, therefore, will depend on the S-R mechanism; what the subject does will depend on which response is the dominant one in that particular situation.

Secondary (Learned) Sources of Drive

The basic question here is whether it is possible to take stimulus conditions that normally do not act as sources of drive and, by appropriate procedures, transfer them into learned sources of drive.

Acquired sources of drive derived from strong aversive stimuli A representative experimental paradigm is provided by Miller's (1948, 1951) study of neutral stimuli acquiring fear-arousing properties as a result of being associated with electrical shock (see pp. 717–718). Rats were shocked in a white compartment and allowed to escape into a black compartment. Subsequently, 13 of 25 animals acquired new responses when these were necessary in order to leave the white compartment, even though no further shock was given after the initial experience. These data are consistent with the conclusion that the initially neutral white compartment became a source of drive which energized responses, as a result of the stimuli of the white compartment having been paired with shock. It is frequently assumed that the white compartment now is a conditioned stimulus (CS) which causes a conditioned response of fear.

[5] Hull (1952) did not explicitly suggest that the subject was generally weakened when electrical shock was used as a source of drive.

[6] Food and water deprivations are not independent; water-deprived rats eat less food and food-deprived rats drink less water (see the section on consummatory activities). Attempts have been made to bypass the difficulty due to interaction between hunger and thirst by depriving subjects of either food or water, and then presenting them with other sources of drive, such as electrical shock. These studies on the summation of drive are reviewed in Bolles (1967). How incentive motivation (K), as an alleged general energizer, combines with generalized drive (D) is considered in our section on incentive motivation as a learned source of drive.

Moreover, this point of view predicts that escape from the white compartment (and the fear-arousing stimuli) into the black compartment should be reinforced by motivational-variable offset (that is, termination of the white-compartment cues); and indeed new instrumental responses were learned, apparently on the basis of this reinforcement.

An extensively held view is shared by Brown and Farber (1968, p. 108) when they conclude that: ". . . there is little doubt that the termination of a fear-arousing CS functions as a reinforcer for a wide variety of responses whose occurrence antedates such reactions . . ." and they cite key experimental studies which seem to support their point.

Recently, however, Allison, Larson, and Jensen (1967) have warned against possible misleading and oversimplified interpretations of Miller's results. First, they found in their own experiment that fear conditioning initially depressed speed of escape from one into another compartment in a shuttlebox, relative to nonshocked controls, thus confounding any reinforcement interpretation of the subsequent improvement in performance for experimental subjects escaping a white CS into a black compartment. Moreover, nonshocked controls showed a reliable preference for black over white compartments, both in terms of initial choice and time spent within compartments, so that experimental subjects with a black CS did not show reliable performance improvement for escaping the black CS into the white compartment.

With regard to Miller's (1948) and other studies on avoidance, Bolles (1967) questions whether a really "new" response has been acquired. He argues that on the basis of available data (p. 408) ". . . there seems to be room for considerable doubt whether the rat can learn any arbitrary response in an avoidance situation." Bolles apparently is not only questioning a current view, expressed for example by Brown and Farber (1968), that "a wide variety of responses" can be acquired as avoidance responses; he also suggests (p. 409) that the fear-arousing CS ". . . may merely elicit species specific defense reactions."

In a frequently cited study, Brown, Kalish, and Farber (1951) demonstrated with rats that after a CS had been paired with electrical shock to the feet, startle responses to a sudden intense auditory stimulus (a pistol shot) were enhanced relative to controls for whom the CS had not been paired with shock. This finding is consistent with the view that conditioned fear elicited by the CS acted as a source of generalized drive which energized the indicant or test response, startle. Recently, however, Kurtz and Siegel (1966) found that the amplitudes of startle responses were enhanced (relative to control groups for pseudoconditioning) only by a compound-stimulus CS paired with electrical shock to the rat's feet, but not by the same compound stimulus when it had been paired as a CS with shock to the rat's back. They suggested that foot shock elicited a postural adjustment (crouching) which reduced the severity of the shock. In the presence of the CS for foot shock, on test trials without shock, the rats maintained a crouching posture which apparently heightened startle responses. The crouching posture was not maintained in the presence of the same compound stimulus when it had been paired with back shock, nor in the presence of the same compound stimulus when it had not been paired with shock in the two control groups for pseudoconditioning.

> In seemingly good correspondence with the postural data, startle responses tended to be about equal in the back-shock experimental group and in the back-shock and foot-shock control groups for pseudoconditioning, but about 50 percent larger in the foot-shock experimental group. Kurtz and Siegel granted the possibility that back shock might have produced postural adjustments which tended to reduce the amplitude of startle responses (and presumably that the conditioned postural response might negate the energizing increment due to fear as a source of drive). They noted, however, that acceptance of this possibility serves to underscore the important influence of posture on the magnitude of startle responses, and to question the generality of the "energization" reported by

> Brown et al. (1951). However, Kurtz and Siegel were not merely questioning the adequacy of the startle response to test for generalized drive. They tentatively suggested that their findings call into question the view of Hull (1943) and Brown et al. (1951) that drive from any source "energizes any and all behavior for which an adequate stimulus is present" (Kurtz & Siegel, 1966, p. 14).

Another apparent difficulty for generalized drive theory is the highly reliable suppression effect in the CER situation (see pp. 712-717 for discussion of this phenomenon). The CS preceding shock is more likely to elicit freezing than enhance or energize the on-going baseline behavior (for example, bar pressing for food or water). Proponents of generalized drive theory might say that cowering tends to be the dominant response for the rat in fearful situations, and that as fear-produced energization increases, so does freezing, and thus overt general activity of necessity decreases. The expression of "more and more vigorous inactivity" appears to strain normal verbal usage, even if it does not actually strain the loosely stated generalized drive formulation.

On the punishment criterion we can only note here that Brown and Farber (1968) cite studies which lead them to conclude that the onset of a CS previously paired with aversive events is punishing (see the discussion of "secondary punishment," pp. 719-720).

A key point may be emphasized by including these comments from Brown and Farber (1968, p. 110):

> "... the energizing criterion, loosely stated as it is, does not require that every response in an animal's repertoire be augmented by the CS under test. Nor is such an outcome expected, even by those who still hold to a generalized drive theory, simply because substantial weight must always be given to the associative properties of any CS. Whenever the energizing criterion is met one is obliged to consider the possibility that the outcome is due to facilitative responses evoked by the CS. Likewise, when it is not met, a search for interfering tendencies is also mandatory."

Careful analyses of the associative properties of any CS are needed as well in tests of reinforcement by CS offset. A major general theme of this chapter is the need to assign a very important role to associative analyses of any situation alleged to involve generalized drive.

Acquired sources of drive from deprivation states In a paradigm somewhat comparable to Miller's (1948) experiment, Myers and Miller (1954) attempted to establish an acquired source of drive based on hunger. Food-deprived rats were placed in a white compartment, and supposedly this CS (white-compartment stimuli) should have become associated with the hunger state. Moreover, the food-deprived subjects learned a door-touching response that opened the door and provided access to food in the black compartment. Four groups were given 0, 10, 30, and 70 "drive-acquisition trials" respectively. Later these subjects were tested when satiated on food. At this time there was no food in the apparatus. Access to the black compartment was now contingent on performing a new instrumental response (bar pressing). It was hypothesized that the white compartment stimuli as a CS would instigate hunger (act as a source of drive), and that CS offset (escape from the hunger-eliciting CS) would reinforce bar pressing. Spaced testing trials were used (one a day). The control group and the three experimental groups performed the required instrumental activity about equally quickly. Thus the effect could not be attributed to an acquired source of drive based on hunger. Myers and Miller (1954) performed a second experiment which revealed that opportunity to explore the new compartment was involved; this was true for both the white-to-black and the black-to-white groups. Moreover, in the second experiment, instrumental responses were performed less often during massed trials (approximately 3-min intertrial intervals) presumably because the second compartment lost its novelty and incentive value. As a consequence, they entitled their experiment, "Failure to find a learned drive based on

hunger; evidence for learning motivated by 'exploration.' "

Although negative findings predominate, the issue might be said to be still in doubt, since some suggestive evidence for an acquired source of drive based on hunger was obtained by Calvin, Bicknell, and Sperling (1953). Rats were food-deprived for either 1 hr (WD = weak drive) or 23 hr (SD = strong drive) and then placed in striped boxes for 30 min daily for 24 consecutive days. Food consumption was subsequently tested with all subjects at $11\frac{1}{2}$ hr of food deprivation. On the assumption that the striped boxes would arouse higher acquired drive in SD than WD subjects, one would predict that more food would be eaten by SD than WD subjects when both groups were tested at $11\frac{1}{2}$ hours deprivation. The expected result occurred at a significant level of confidence. Siegel and MacDonnell (1954) repeated the Calvin et al. (1953) study; they found no reliable group differences, and the trend was even in the opposite direction: the WD group had slightly larger mean food intakes than the SD group during test trials. Brown and Farber (1968) cite other negative findings and emphasize that even with the positive results found in the Calvin et al. type of study, unambiguous interpretation is not possible because satiation (that is, at 1-hr food deprivation) in the WD group may have, by association with the striped boxes, depressed food intake on the test trials. We must agree with their conclusion that as yet there is insufficient evidence to support the hypothesis that acquired sources of drive can be based on the association of any CS with the presence of deprivation states such as food or water deprivation.

Incentive motivation (K) as a learned source of drive In the introductory section illustrating motivational effects it was shown that performance speed can be increased or decreased by appropriate shifts in either deprivation time or amount of reinforcer. Such rapid shifts in performance were interpreted by most theorists as due, not to rapid learning and unlearning of how to run in the runway, but to shifts in the motivational level energizing behavior. Of course, such theorizing required that reinforcer magnitude be conceived as a determinant of motivation during a trial, and that previously neutral stimuli that have been paired with the reinforcer would now be able to energize behavior before the subject was actually exposed to stimulation from the reinforcer on that trial. It is primarily this anticipation of the reinforcer as an alleged source of drive that is our concern here; other aspects of positive reinforcement are discussed in Chapter 15.

We will start with a review statement of several assumptions typically made within the Hull-Spence S-R theory of r_g. It has been assumed that various consummatory (goal) responses (R_Gs) have components which can become classically conditioned to goal box stimuli and perhaps to internal deprivation stimuli. Some of these conditioned fractional goal responses (such as salivation), because of stimulus generalization, may be elicited by runway stimuli and occur as fractional anticipatory goal responses (r_gs) during the trial and before exposure to the food stimuli in the goal box on that trial. An r_g, like any response, is assumed to have some sensory effects. In addition, this r_g–s_g mechanism has been assumed (Spence, 1951, 1956; Hull, 1952) to be a source of incentive motivation (K). The r_g–s_g–K mechanism has been proposed within S-R theory to deal objectively and systematically with "expectancy" or anticipation of a reinforcer. With regard to this r_g–s_g–K formulation, we need to know the strength of r_g, which determines the magnitude of K.

> Since it is assumed (Spence, 1956) that r_g is a classically conditioned response, the habit strength of r_g should be assumed to vary with the number of conditioning trials in the goal box. In addition, characteristics of the goal object (such as amount of food) which produce unconditioned consummatory or goal responses (R_Gs) of different vigor may contribute to either the habit strength of r_g or to the conditioning of different responses, each with its characteristic

vigor. Moreover, the similarity of cues outside the goal box to those in the goal box will influence the strength of r_g elicited at various distances from the goal box.

K should be expected to vary with changes in deprivation as well as with changes in the reinforcer. Brown and Farber (1968) note that internal consistency within Hull-Spence S-R theory would seem to require that D energize both R_G and r_g. Higher D values should produce stronger R_Gs, which in turn should lead to stronger conditioned r_gs, and these stronger r_gs should be energized still further by D, resulting in higher K values. This logic makes K in part a function of D, which in turn makes K in part a function of deprivation time. If D were zero, according to this view, r_gs would not occur because they were not being energized, and K should be zero. However, it should still be possible to have demonstrable D levels in situations idealized as being completely devoid of incentive motivation, that is, in a situation devoid of any effective external cues to elicit conditioned generalized r_gs, and perhaps with subjects devoid of experience with various deprivation schedules in order to minimize generalized r_gs conditioned to internal deprivation cues.

There are experimental data which are consistent with the view that the r_g-s_g-K mechanism is in part a function of deprivation. For example, Kintsch (1962) used three degrees of water deprivation and three amounts of water as reinforcer. Figure 18.3 shows the obtained asymptotic starting speeds in a runway as a function of the nine combinations. The differences between low, medium, and high amounts of water as reinforcer are minimal at low deprivations and maximal at the highest deprivation used. In this example at least, incentive motivation apparently interacted with degree of deprivation. However, the more typical finding seems to be that an analysis of variance reveals no reliable interaction between the deprivation and reinforcer magnitude variables, except in studies which employed a zero value for at least one of these variables (Black, 1965; Bolles, 1967).

An experimental demonstration that r_g functions as a secondary source of generalized drive, in accordance with the systematic approach we adopted earlier, must fulfill at least one of the three criteria for identification of a motivational variable. It should be possible to show that the onset of an r_g-evoking CS punishes antecedent responses, and/or its presence energizes concurrent responses, and/or its cessation reinforces antecedent responses.

Brown and Farber (1968) concluded that the r_g mechanism probably cannot fulfill the punishment criterion, since eating food is drive-reducing and tranquilizing, and that therefore it is unlikely that conditioned cues for food would not be tranquilizing as well. The experimental paradigm that allegedly conditions a CS to elicit an r_g is the same classical conditioning procedure of pairing a CS with food that allegedly makes the CS a secondary reinforcer. Studies of secondary reinforcement have shown that, after CS-food conditioning, CS onset alone enhances but does not generally weaken instrumental responses (see pp. 660–677).

Figure 18.3. Asymptotic starting speeds (reciprocals of latencies) in a runway for all combinations of 3 levels of water deprivation (drive) and 3 amounts of water as a reinforcer. The lowest set of curves on the left show that, with the smallest reinforcer magnitude, variations in drive level had minimal effects on performance; similarly (lower right) at the lowest drive level, variations in reinforcer magnitude had minimal effects. The top set of curves on the left show that, with the highest reinforcer magnitude, performance varied markedly with drive level: high drive (HD) was best, low drive (LD) was poorest, and medium drive (MD) was intermediate. Similarly (top right) at high drive, performance varied markedly with reinforcer magnitudes: highest reinforcer magnitude (HR) was best, lowest reinforcer magnitude (LR) was poorest, and medium reinforcer magnitude (MR) was intermediate. The left, middle set of curves show that, with a medium reinforcer magnitude, performance was best at high drive and latencies at low and medium drive were interchangeable. Similarly (middle right) at medium drive, performance was best with the highest reinforcer magnitude, and latencies were interchangeable for the medium and lowest reinforcer magnitudes. (Kintsch, 1962.)

The reinforcement criterion requires that an instrumental response should be reinforced when it is followed by the offset of the CS which elicits r_gs. Brown and Farber (1968) commented that it seemed unlikely that the r_g mechanism could fulfill this criterion, although apparently this particular test has not been made.

The third criterion is that the presence of a motivational variable functions as a nonspecific generalized energizer of responses. Several attempts have been made to circumvent associative interpretations of motivational effects attributable to a food-associated CS by the use of a response believed to be, in the history of the subject, entirely independent of both the r_g-eliciting CS, and the reinforcer used to establish incentive motivation. Specifically, amplitude of a startle response was selected to test for generalized drive because presumably startle responses have not been associated with get-food behavioral patterns, nor reinforced with food. The experimental paradigm employed has been a classical conditioning procedure for a large number of trials (CS paired with food as the UCS), and the evocation of startle responses with a cap pistol shot, both in the presence of the CS and in its absence.

In one such study, Trapold (1962) found that the experimental group conditioned with 24 percent sucrose as UCS made reliably more approach responses to the food location between CS and UCS onset than the experimental group conditioned with 6 percent sucrose, and both experimental groups had markedly more "instrumental" responses than the control group. In other words, the relation between instrumental responses and reinforcer magnitude (concentration) usually attributed to r_g as a general energizer was present in this experiment. However, the startle-amplitude measure was *not* reliably different for the three groups. Therefore, there was no evidence that the supposedly r_g-evoking CS enhanced startle responses during the conditioning trials when the CS did enhance instrumental responses. Moreover, Armus, Carlson, Guinan, and Crowell (1964) and Armus and Sniadowski-Dolinsky (1966) found that a food-associated CS actually lessened the size of the startle response. Thus, these experiments provide no support for the view that an r_g-evoking CS serves as a general energizer; instead, they tend to favor the view that the CS paired with food has become a secondary reinforcer which *reduces* generalized drive.

It may be premature, however, to discount the possible influence of postural and instrumental responses on the apparent reduced size of startle in the presence of a secondary reinforcer. For example, if one happened to utilize conditions that led rats to maintain a crouching posture during the CS-food conditioning, then a CS-elicited crouching posture might enhance startle responses, as it did in the Kurtz and Siegel (1966) study of fear as a source of generalized drive. The use of startle responses to test for generalized drive requires better control and understanding of the influence of postural and instrumental responses on startle magnitude than we now have.

The conclusion that stimuli which precede positive reinforcers are tranquilizing or drive-reducing appears to be contrary to observations that the general activity of animals increases immediately before their normal feeding time. Presumably such activity is not merely a function of deprivation, but is in part controlled by the presence of cues associated with feeding. Experimentally, Sheffield and Campbell (1954) demonstrated heightened stabilimeter activity in the presence of a five-minute CS when its termination was followed by food, but not for controls when the CS termination was not paired with feeding. Here is a seeming paradox: presentation of food-associated stimuli sometimes increases and sometimes decreases instrumental activity. Perhaps such stimuli "energize" only certain subsets of responses (such as get-food responses). In this case, the concept of generalized drive may itself be at fault and D may need to be replaced by multiple, specialized energizers. For example, Bindra and Palfai (1967) found that, after classical conditioning

of restrained rats, a water-linked CS enhanced perambulation whereas a shock-linked CS enhanced "sitting" (crouching), with apparently compensatory changes in the time spent grooming in the presence of either water- or shock-linked CSs. Such data are not readily reconciled with a single general energizer. Bindra and Palfai interpreted their data as supportive evidence for two central drive states: a positive incentive-motivational central state that is related to appetitive functions, and a negative incentive-motivational central state that is related to defensive functions. The case for viewing incentive motivation as classically-conditioned central drive states is developed further by Bindra (1968), and by Rescorla and Solomon (1967). These approaches represent a strong agrument against the continued acceptance of the concept of incentive motivation as a source of generalized drive which energizes all responses. Even one of the major proponents of generalized drive theory (Brown, 1961) has recently proposed a graduated-drive theory that drastically changes the properties of a general energizer.

According to the graduated-drive theory, ". . . all habits are multiplied by the drive arising from any source, but *the numerical value of the multiplier is graduated according to the relevance of the response to the motivational variable*" (Brown, Anderson, & Brown, 1966, p. 400, italics in the original), These recent developments favor replacing the concept of a generalized energizer with some degree of selective energization of responses, but leave the experimenter with the knotty problem of deciding the relative relevancies of responses.

To recapitulate, we can conclude that neither theoretical considerations nor experimental data support the r_g-s_g-K formulation of incentive motivation as a source of generalized drive. The contemporarily very important research area of incentive motivation has provided evidence that considerably extends the range of plausible associative accounts of motivational effects attributed to reinforcer-linked CSs, and recent developments favor the likelihood that responses are selectively energized by multiple central drive states.

Frustrative nonreinforcement as a source of drive Our discussion of frustration will be limited and guided by a question which initially can be put loosely as follows: Do unfulfilled expectancies of reinforcers serve as primary or secondary sources of drive? An influential experimental demonstration of the basic "Frustration Effect" was provided by Amsel and Roussel (1952).

> Their standard two-runway situation has been much used since; alley one (A_1) and its goal box (G_1) are linked in series with alley two (A_2) and goal box two (G_2). The major dependent variable is running time (or speed) in the second alley (A_2). Food-deprived rats were run with food in both goal boxes until running speeds apparently reached a stable maximum. Next, food was absent in G_1 on half of the trials, but food was still always present in G_2. The initial 8 trials of intermittent reinforcement in G_1 revealed that A_2 performance differed very little between the 4 test trials (food absent in G_1) and 4 control trials (food present in G_1). On the remaining 28 trials of 50 percent reinforcement in G_1, 14 paired comparisons revealed that the median A_2 running times were shorter on each test trial than on its control trial. Since A_2 running times were shorter on test trials than on any other trials in the entire experiment, apparently performance in A_2 was energized when the customary food was absent in G_1. The greater vigor of A_2 performance on test than on control trials has been referred to as the Frustration Effect (FE), and the FE is used as an indicant of a primary frustration reaction (R_F) which is evoked in G_1 by the absence of an anticipated reinforcer. To account for the absence of a clear FE on the first four pairs of test and control trials, Amsel and Roussel suggested that several test trials may have been required to reduce the effectiveness of secondary reinforcers in G_1 sufficiently to permit the appearance of the FE. Acceptance of this explanation for the absence of the FE on test trials 1-4 would evidently permit one to maintain that the omission of a customary primary reinforcer immediately gives rise to an unlearned, primary R_F.

The view that anticipation of reinforcement is a prerequisite for frustrative nonrein-

forcement has been supported by the more gradual development of the FE during intermittent reinforcement from the onset of the experiment than after continuous reinforcement (Roussel, 1952, cited by Amsel, 1958; Amsel & Hancock, 1957; Wagner, 1959). Amsel (1958, 1962, 1967) has retained the basic Hull-Spence r_g formulation of anticipatory goal responses; however, he has used r_R to symbolize conditioned fractional anticipatory responses derived from the responses to the positive reinforcer (such as food) in the goal box, and r_F to symbolize the conditioned anticipatory form of R_F.

This view that r_Rs are prerequisites for the FE would predict that r_R (and therefore the FE) would be stronger when A_1 and G_1 cues are similar than when they are different (because the more A_1 cues resemble G_1 cues, the more effectively A_1 cues can elicit conditioned r_Rs with less stimulus generalization decrement). Amsel and Hancock (1957) did indeed find that the FE was larger when both A_1 and G_1 were white than when a black A_1 was used with a white G_1.

A related prediction is that, because the strength of r_R is a function of reinforcer magnitude in G_1, the size of the FE due to frustrative nonreinforcement should depend in part on reinforcer magnitude in G_1. To test this, Peckham and Amsel (1964) used a within-subjects design wherein two brightnesses (black or white) of A_1 were cues for either 8 or 2 pellets in G_1. With the usual FE measure (A_2 speed after G_1 nonreinforcement minus A_2 speed after G_1 reinforcement), they found reliably greater FEs after omission of 8 than omission of 2 pellets in G_1.

On the other hand, if G_1 food is reduced but not eliminated on test trials, speed in A_2 is inversely related to the amount just eaten in G_1 (Barrett, Peysey, & McHose, 1965; McHose & Ludvigson, 1965). A drive-reduction interpretation of this situation would lead to the prediction that hunger and A_2 speed would be reduced in proportion to the amount of food ingested in G_1. Such a drive-reduction hypothesis could not account for the FE observed with complete reduction of reinforcer magnitude to zero on test trials (Wagner, 1959; Peckham & Amsel, 1964). However, McHose and Ludvigson suggested that the drive-reduction hypothesis most readily fits their data on incomplete reduction of reinforcer magnitude to above zero values. McHose and his colleagues (1965) note that there is room for doubt that Bower's (1962) findings demonstrate the FE is graded in proportion to the extent of reduction in reinforcer magnitude. Although A_2 response vigor was proportional to the extent that an initially large amount of food in G_1 was subsequently reduced, this may be due in part to depression of A_2 performance in proportion to the amount of food ingested in G_1. Appropriate controls are required to distinguish between the FE genuinely attributable to frustrative reinforcer-magnitude reduction in G_1 and the effects of reinforcer magnitude in G_1 on A_2 performance without reinforcer magnitude shifts, and therefore presumably without any reason for an assumption of an R_F.

Marx (1956) suggested that the FE can be accounted for by a strictly associative interpretation. For example, Marx referred to a pilot study of rats reared in overcrowded social cages in which it may be assumed that competitive behavior was probably differentially reinforced. A later test for frustration seemed to indicate that increased vigor (supposedly as in the FE) was at least in part due to transfer from prior learning to react to frustration with more vigorous responses. Amsel and Penick (1962) extended this investigation to include three experimental variables: litter size, conditioned activity or inactivity, and inaccessible food (shielded by a wire cover). Tests for the FE in the double runway did not support the hypothesis that prior learning to respond vigorously would transfer to this situation in the form of larger FEs. Instead, the inaccessible food initially tended to elicit a variety of responses directed at obtaining the food (such as biting and clawing through the screen), and these responses interfered with the FE. In other words, this study found that the FE could be *reduced* associatively by specific competing responses, but it apparently failed to find any evidence that the FE was increased by the particular associative variables investigated in this experiment.

It seems reasonable to conclude that the FE by itself is not definitive evidence for the view that frustrative nonreinforcement is a primary source of generalized drive, although the use of additional response measures be-

sides runway performance and bar pressing might improve the argument for generalized drive. Particular requirements for the further elucidation of frustrative nonreinforcement might include a more adequate description of the various R_Fs, their sensory and associative effects, and further tests with a variety of responses to assess whether a particular R_F qualifies as a source of generalized drive or as a source of a more restricted energizer which enhances only some subset of responses.

More direct tests have been made of conditioned frustration as a secondary source of drive. For example, Wagner (1963) has shown that a CS paired with frustrative nonreinforcement fulfilled two criteria for the identification of a motivational variable: its presence temporarily enhanced a startle response and its offset reinforced hurdle responses. Replication and extension of this research would be especially valuable because it has apparently provided the most direct test of basic assumptions concerning the properties of a CS linked with frustrative nonreinforcement.

Recently, Wagner (1966) has reviewed evidence for the view that nonreinforcement and punishment often have similar effects, although their over-all effects are not necessarily identical. For example, approach responses have been reduced by punishing electrical shocks and by frustrative nonreinforcement, and alcohol reversed both these effects. In another study, training to approach a goal box in the presence of conditioned fear subsequently transfered when approach was tested in the presence of conditioned frustration, and vice versa. Such evidence supports the view that when a CS has been linked with frustrative nonreinforcement, the CS is reacted to as an aversive stimulus (that is, in some ways the CS has become comparable to electrical shock). Therefore, we might tentatively conclude that a CS linked with frustrative nonreinforcement represents an aversive condition which has fulfilled at least two of the criteria for identification of a motivational variable.

Response-defined Level of Drive

Brown (1961, pp. 35–40) considers four objective ways to define drive which avoid circular "explanations" of behavior. Two of these refer respectively to antecedent conditions (such as deprivation times) and stimulus conditions (such as strength of electrical shock used as UCS), both of which presumably can and should be manipulable independently of the dependent variable they allegedly influence. The third class of objective definitions are organismic and/or physiological measures (such as body weight deficit, blood sugar level, hormonal level, or heart rate); some of the physiological measures in this third category are classifiable as responses. Fourthly, a behavioral response measured in one situation can be used as an index of drive in other situations provided at least one of the criteria for a motivational variable can be fulfilled. Examples of possible response-defined indices of motivational level are amount of food consumed, over-all general activity as seen in a stabilimeter, activity wheel measures, or the score on a standardized paper and pencil test such as Taylor's manifest anxiety scale (Brown, 1961, pp. 253–263). In considering the relative merits of these four ways of "defining" drive within contemporary drive theory, we should recall that needs and drive must be distinguished, that associative explanations of "motivational effects" must always be considered as possible alternatives to alleged motivational ones, and that a significant definition of a source of drive requires satisfying at least one of the criteria for motivational variables. Brown and Farber (1968) note, for example, that muscle tension may be a useful measure in drive research, provided it can meet the motivational criteria, even when the stimuli eliciting muscle tension cannot be precisely specified. Brown (1961, pp. 238–239) defends the principle of response-defined drive levels, including the selection of subjects on the basis of test scores. He concludes (p. 239): "No one can predict, at present, which of the many varie-

ties of each method will ultimately yield the most useful and significant estimate of drive, nor whether one of the methods will ultimately prove to be better than the other."

CONSUMMATORY ACTIVITY AS AN INDEX OF DRIVE

Although deprivation procedures have been used extensively and effectively "to motivate" laboratory animals to some unknown degree ("low" or "high") in a wide range of psychological experiments during past decades, the precise quantification of deprivation-produced generalized drive has continued to be difficult to achieve. On the assumption that generalized drive energizes all responses, we may seek quantitative descriptions of how dependent variables such as consummatory and instrumental responses are related to the independent variable of degree of deprivation. Any consistent pattern in such studies may permit one to infer how the alleged energizer of these responses, generalized drive, increases with degree of deprivation. With this purpose in mind, consummatory measures will be discussed here; the next two sections will be devoted to general activity and instrumental responses.

Definition and Measurement of Degree of Deprivation

Before we examine consummatory activities as a function of degree of deprivation, we must first consider how to define and measure the degree of deprivation. Deprivation time (hours of food or water deprivation) has frequently been used as an operational measure of the degree of deprivation, with the intensity of the deprivation-produced drive level being inferred from deprivation time. The extensive use of deprivation time to produce various drive levels may be largely attributed to its apparent simplicity and ease of use, but in part it is due to the influence of Hull (1943, 1952) and Spence (1956), since many experiments have been performed to investigate their theoretical formulations. However, there also is good evidence for the view that relative body-weight loss may provide a better index of degree of either caloric or water deprivation (Stolurow, 1951; Ehrenfreund, 1959; see review by Bolles, 1967).

Physiological approaches to the determinants of food intake have tended to emphasize the homeostatic regulation of caloric intake in relation to energy expenditures (Anand, 1961; Grossman, 1967). In support of such an energy balance, Anand (1961) observed that, even when energy outputs vary greatly, most adults maintain a constant weight, and young animals "grow at well-defined rates." The inference was made that food intake varies in accordance with caloric requirements, and "that two types of regulation are at work. The first, and most important, is the short-term regulation, which adjusts from day to day the calories eaten to calories spent. The second, long-term and working slowly, corrects over a period of time whatever error of which the rapid mechanism is guilty" (p. 692). In the study of Adolph (1947), for example, when nonnutritive roughage was mixed with food, rats increased the total bulk eaten, whereas the utilizable nutrients consumed did not exceed the control values.

From this view of the regulation of food intake in terms of energy balance, one might expect that the degree of any imposed caloric deprivation should be reflected in a body-weight deficit. Moreover, many variables which influence metabolic rate, and therefore energy expenditures, would presumably be reflected in the observed body-weight deficit. Hence, differences in body weight, age, sex, and environmental conditions (such as temperature, humidity) which influence energy expenditures (Kleiber, 1961) may confound the interpretation of *X* hours of food or water deprivation. For example, with the same food-deprivation times, the percentage weight loss of young rats will be much greater than that of more mature animals (Campbell,

Teghtsoonian, & Williams, 1961). Similarly, to produce any given percent weight deficit requires longer deprivation periods for older animals (Bolles, 1965b), and the effects of water-deprivation times on relative weight deficits vary with age (Campbell & Cicala, 1962).

Bolles (1965b) found that the percentage weight loss was a linear function of food-deprivation time when both were plotted in log units. Groups of different ages had power functions with similar slopes but, as noted above, the same deprivation time produced markedly different relative weight losses for the various ages. On the basis of these results one might expect that, under standard conditions, the percentage weight deficits may be estimated from deprivation times. This may often be difficult to do for published studies, however, which vary significantly in species, strains, age of subjects, and in the experimental conditions. In the present context, the essential point is that consummatory responses, general activity, and instrumental responses may be found to be more consistently and precisely related to relative body-weight deficits than to deprivation times. It is in this sense of providing a more concise and coherent description of the behavioral data that the relative body-weight deficit may be considered as the more useful index of the degree of deprivation and of the magnitude of the deprivation-produced drive.

Consummatory Measures as a Function of Degree of Deprivation

Water deprivation Siegel (1947) found that the water intake of male rats increased monotonically as a function of hours of water deprivation up to 48 hr (Figure 18.4), although the 5-min water intakes were not reliably different for 24 and 48 hr deprivation. Siegel also noted that percentage body-weight deficit was a rising monotonic function of hours of water deprivation, and that water intake increased monotonically with size of percentage weight loss.

A wider range of water deprivations were studied by Stellar and Hill (1952) with an electronic drinkometer that provided cumu-

Figure 18.4. Mean 5-min water intake in milliliters as a function of water-deprivation times. Separate subgroups of rats were tested once at 6, 12, 24, or 48 hr of deprivation. Five-minute water intakes after 24 and 48 hr of deprivation were not reliably different. (Siegel, 1947.)
Figure 18.5. Mean cumulative water intake throughout 2 hr of 4 rats tested under each of the water deprivation times. Total water intake for 120 min increased monotonically with hours of water deprivation: 6 (lowest curve), 12, 24, 48, 96, and 168 (highest curve). (Stellar & Hill, 1952.)

lative curves of the temporal course of drinking during the 2-hr test period. Four 5-month-old male rats were habituated for a month to the living situation and then underwent an increasing series of water deprivations, each of which was separated by a period of *ad libitum* feeding and drinking until recovery from any previous weight deficit. The mean water intake during the 2-hr test was an increasing monotonic function of deprivation between 6 and 168 hr of water deprivation (Figure 18.5). Stellar and Hill (1952) also reported that regardless of deprivation times, the rat either does not drink or drinks at a constant rate of 6 or 7 tongue laps per sec (cf. Keehn & Arnold, 1960; Schaeffer & Premack, 1961; Collier, 1964). (The constancy of drinking rate is not seen in Figure 18.5 because the momentary intakes of four rats were averaged before plotting.) For deprivation periods of more than 6 hr, fairly constant drinking occurred for at least 5 min; after longer periods of drinking, the frequency and the duration of pauses distinguished the effects of varying degrees of deprivation. Hence, intake during a brief test period is unlikely to reflect differences among longer deprivation periods. On the other hand, readiness to drink in a novel situation does continue to increase over longer deprivation periods. For example, Bolles (1962) found that as deprivation times increased up to 96 hr, latencies to drink decreased proportionately without any evidence of inanition (Figure 18.6).

Figure 18.6. Median latency to start drinking water for naively thirsty rats (that is, upon initial deprivation) when tested after water deprivations of 4, 24, and 96 hr. The lowest "deprivation" time is the time to start drinking water in the test situation after removal from the *ad libitum* conditions in the home cage (that is, without an experimentally imposed deprivation). Note that both deprivation times and drinking latencies are on logarithmic scales. (Modified from Bolles, 1962.)

A somewhat different behavioral index of the severity of water deprivation is based on the observation that a rat's water intake can be reduced or completely suppressed by the addition of quinine hydrochloride, a substance which humans call "bitter." For example, after various hours of water deprivation, Campbell and Cicala (1962) measured the 24-hr consumption of 0.001M quinine solution by experimental subjects and water intake by equally deprived controls. They found that intake of the quinine solution was almost completely suppressed at zero weight loss. As the weight loss increased up to 30 percent, reflecting increasingly severe water deprivation, 0.001M quinine became less and less effective in suppressing drinking. A single inverse function represented quite well the averaged data based on weight deficits of 25-day-old rats water deprived for 0, 24, 48, or 72-hr and 100-day-old rats water deprived for 0, 24, 48, or 192 hr. (The implications for a concept of generalized drive of these studies on water intake will be discussed after the presentation of related studies of food intake.)

Food deprivation In one of the earlier experiments on food intake at different deprivation times, Bousfield and Elliott (1934) maintained rats for at least three weeks on a feeding schedule of daily access to a liberal supply of food between 9:30 A.M. and 10:30

A.M. Subsequently, they introduced delays in the feeding hour and they found that after 24- and 48-hr delays (that is, after 47 and 71 hr of food deprivation) the 1-hr food intake was approximately 86 and 74 percent, respectively, of the amount eaten after the regular 23-hr deprivation. Water was available at all times. After each delayed feeding, animals were returned to the regular 23-hr deprivation schedule for at least a week. Bousfield and Elliott suggested that changes in the stomach's tonicity reduced capacity after the longer deprivations. Measurements of eating rate demonstrated that at the longer deprivations (47 and 71 hr) the rats not only ate fewer pellets, but ate them more slowly, and "more steadily and persistently." In summary, Bousfield and Elliott found that when rats were maintained on a 23-hr food deprivation schedule, longer deprivation times and presumably greater body weight deficits were accompanied by significant reductions in rate of eating and amount consumed. Recently, Dufort (1964b) confirmed that 1-hr food intake is less after 47 or 71 than after 23 hr of food deprivation, even though these 6-month-old rats apparently never had any prior exposure to a 23-hr food-deprivation schedule. Thus, the decreased intake at the longer intervals does not seem attributable to adaptation to a once-per-day feeding regimen.
Figure 18.7. Mean 20-min food intake of the same group of rats tested at each of the food deprivation times. (Horenstein, 1951.)
Figure 18.8. Mean 2-hr food intake for a separate group of 4 rats for each food-deprivation time tested. Each rat had no past history of deprivation and it was tested only once. (Dufort & Wright, 1962.)

On the average, food intake during test periods increases as deprivation time increases up to about 24 hr without food, for both highly experienced animals (Figure 18.7) and animals tested with but one deprivation condition (Figure 18.8).

In the later section on instrumental behavior we refer to Miller's (1956) comparison of several behavioral "measures" of hunger. The drinking curve in Figure 18.10 (p. 827) refers to intake of enriched milk until satiation and this measure can be properly considered here under food intake. The nonsignificant decrement from 30 to 54 hours of food deprivation is consistent with the above evidence that food intake (within 120 minutes) does not increase significantly for food deprivations beyond 24 hours. The same figure also shows that, in order to prevent eating, milk had to be adulterated with greater amounts of quinine at higher food-deprivation times.

A modified version of the "quinine measure" described by Miller (1956) was used in a study of food deprivation with 23- and 100-day-old rats (Williams & Campbell, 1961). They found that the quinine suppression of

milk intake was inversely proportional to percent weight loss (in other words, a constant concentration of quinine prevented milk intake to a lesser extent at higher deprivations). The functional relation of intake and percent weight loss was the same for both age groups.

The relation between latency to eat and food deprivation appears to be simpler and more orderly than some of the other measures considered. Bolles (1962) assigned separate groups of rats to 0, 4, 24, 72, and 96 hours of food deprivation. When latency to eat was plotted versus the independent variable of deprivation time on a log-log scale, the result was an inverse linear function. A power function was also found when latency to eat was plotted against percentage body-weight loss for male and female rats of different ages (Bolles, 1965b). For the pigeon as well, readiness to eat was found to be directly proportional to body-weight loss (Megibow & Zeigler, 1968).

Interactions of food and water deprivations Although there are important species differences, for man, rat, and some other species, food intake is reduced during water deprivation, and water intake is reduced during food deprivation. The extensive physiological literature and some of the psychological studies are discussed in Wolf's (1958) comprehensive treatment of thirst.

Verplanck and Hayes (1953) emphasized that, for learning experiments involving the summation of drive from food deprivation and from water deprivation or the discrimination between food and water deprivation, it is important to note that food and water deprivations are not independent. Their data supported the conclusion that water-deprived rats eat less food and food-deprived rats drink less water than when both food and water are freely available. As a result, body weight declines when either food or water intake is restricted (Dufort, 1963b), with the major portion of the weight deficit during water deprivation accounted for by the amount of reduction in the intake of freely available food (Collier, 1964; see also Campbell, 1964).

For behavioral studies under standard laboratory conditions, weight deficits may continue to be one of the more useful indices of the degree of deprivation produced by withholding either food or water. Eventually it may be possible to calibrate weight deficits in terms of more fundamental physiological measures of deprivation severity and correlate these measures with consummatory activity (see, for example, Corbit, 1969).

Implications for generalized drive Do studies of food and water intake provide a satisfactory basis for inferring how the magnitude of drive varies with degree of deprivation? Differences between the various tests of ingestion, and between ingestion measures and latency scores, indicate that, on the basis of consummatory activity, we cannot construct even an ordinal scale of drive that would have general applicability (see Brown, 1961, p. 53, and Bolles, 1967, pp. 160–161). There thus is little evidence here for a concept of a unitary, generalized drive associated with food or with water deprivation.

Associative Influences on Consummatory Activity

Reinforcement of consummatory responses Would a consummatory activity such as eating extinguish in the sham feeding situation (see pp. 620, 627), if eating were not followed by primary reinforcement from need reduction? Such extinction apparently failed to occur in some of Pavlov's experiments (Rosenzweig, 1962). This apparent lack of extinction of sham feeding is in sharp contrast with the observations of Hull, Livingston, Rouse, and Barker (1951) in a pilot study with one dog. They found that the dog "ate" very large quantities of gruel during the first few days (three-quarters of its body weight per session). Consumption diminished to a few licks by the eighth day. This experimental extinction of eating was apparently associated with particular cues in the experimental room

because outside the experimental room the dog sham fed again.

At one point Pavlov had mentioned feeding his dogs meat, so perhaps differences in foods used might partly account for the contrast in results. Eating responses might be reinforced by taste as well as by need reduction. It is not clear that one can rule out the possibility that eating may have been intermittently reinforced for Pavlov's dogs by having sham feeding associated with the absorption of food which had been placed directly into the stomach via the other esophageal fistula (analogous to the effect reported by Smith & Capretta [1956] on saccharin)

The fact that the extinction of sham eating was apparently specific to cues in the experimental room could be interpreted as indicating that either the punishment resulting from occasional clogging of the upper fistula and resultant retching and gagging, or the lack of positive reinforcement from drive reduction, could have become associated with particular experimental cues. If either of these interpretations were confirmed, it would illustrate associative effects modifying eating.

Premack (1965) has demonstrated that the consummatory activities of eating and drinking can be reinforced by other activities. For example, access to a pinball machine was made contingent on the prior consumption of candy by children who preferred playing with a pinball machine to eating candy. Under these conditions Premack (1959) found that the increased intake of candy was significantly greater than in a control group with the reverse contingency. In another experiment (Premack, 1962), rats' water drinking was markedly augmented when limited access to an activity wheel was made contingent on prior drinking responses. It appears reasonable to conclude from such observations that at least some aspects of consummatory activities are modifiable by reinforcement.

Effects of taste on consummatory measures Some degrees of sweetness enhance intake measures, but the effect interacts with caloric deprivation. Food-deprived rats consume much more nonnutritive saccharin solution than nondeprived controls (Sheffield & Roby, 1950), and similarly, the intake of a diet with saccharin added is much greater for food-deprived than for nondeprived dogs (Jacobs & Sharman, 1969). It appears that the degree of enhancement of intake by saccharin interacts with the degree of food deprivation.

Quinine (presumably because of its bitter taste) depresses intake measures, and again there is an interaction with deprivation. For rats, intake of food or water adulterated with quinine is proportional to the degree of deprivation (Williams & Campbell, 1961; Campbell & Cicala, 1962). For dogs, on the other hand, food deprivation seems to increase reactions to quinine (Jacobs & Sharma, 1969).

Taste properties of a high-fat diet can enhance the rat's food intake as well. Rats had a higher caloric intake and gained weight at a greater rate on a high-fat diet than on laboratory chow pellets. When the pellet diet was matched for caloric density with a mineral oil diet which had the taste properties of the high-fat diet, again the caloric intake was greater for mineral oil than pellets. These taste effects were accentuated and quite large in rats with obesity resulting from lesions in the ventromedial hypothalamus (Corbit & Stellar, 1964). In this context, it may be interesting to note that obese humans ate larger amounts of high-quality ice cream and smaller amounts of low-quality ice cream than subjects who were either of normal weight or underweight (Schachter, 1968).

Since the effects of taste on consummatory responses are large under some conditions, and since they interact with other variables (such as deprivation, obesity, or novelty) in a complex manner, a single general statement about the magnitude of the effect of taste on consummatory measures cannot be made: it depends on the test conditions.

Practice effects and "adaptation" to deprivation schedules The main question considered here is whether specific degrees of deprivation produce particular internal depriva-

tion stimuli that selectively form associations with specific consummatory responses.

Our analysis is made more difficult by the fact that there are at least three types of confounding influences which might produce increased consummatory responding after repeated periodic deprivations without involving more and/or stronger associations between internal deprivation stimuli and the consummatory behavior. Briefly, these factors are: (a) cumulative weight deficits produced by repeated periodic deprivations; (b) waning of "novelty reactions" (Bindra, 1959b, 1961) that interfere with consummatory responding in unfamiliar situations; and (c) conditioning of consummatory responses, instrumental approach responses, or central excitatory states to stimuli in the test situation. In this latter case, it seems plausible that reinforcer-linked CSs might elicit central drive states without the mediation of overt behavioral responses, in the same way that CSs acquire reinforcer-linked properties when animals are physically restrained (Bindra & Palfai, 1967) or immobilized by curare (Solomon & Turner, 1962).

A number of studies of "adaptation" to repeated deprivations were directly or indirectly influenced by Hebb (1949), who demonstrated that rats used only a small fraction of the available eating time when first tested after 24 or 48 hr of deprivation. Hebb argued that, in part, the animals had to learn when to eat and when to cease eating, and that need for food and the stimuli from the food were not sufficient to produce entirely appropriate eating behavior.

These observations have been extended and confirmed in subsequent experiments (for example, Ghent, 1951, 1957; Bolles & Rapp, 1965). If the procedure of depriving and testing is continued, rats typically increase their intakes to the point where, with one feeding a day, they are able to maintain stable body weights. Such adaptation to 23-hr food-deprivation routines requires about 2 weeks (Reid & Finger, 1955; Lawrence & Mason, 1956; Dufort, 1964b); with 47- or 71-hr schedules, however, rats fail to stabilize their weights (Dufort, 1964b). With water deprivation, on the other hand, rats do achieve stable body weights when maintained on 23-, 47-, or 71-hr deprivation schedules. The usual interpretation of these experiments is that drive is increasing up to the point where body weight stabilizes. Hence, experiments using food or water deprivation usually maintain the animals on the deprivation schedule until weights stabilize before introducing the main treatment.

A direct test of the view that consummatory responses, such as eating and drinking, are partially under control of previously experienced external stimuli is provided by Fink and Patton (1953). Rats were trained to drink in the presence of one intensity level of sound, light, and tactual stimulation respectively, and then various degrees of stimulus change were introduced by changing the intensity level in 1, 2, or 3 modalities. A balanced design was employed wherein some subjects were shifted from a high to a low intensity level and other subjects had the reverse order. A significant decrement in drinking resulted which was proportional to the degree of stimulus change (that is, changes in 1, 2, or 3 modalities). Decrements in drinking were largest for light changes and smallest for tactual changes. The overall results are consistent with the view that particular stimuli in the drinking situation became water- or reinforcer-linked CSs which facilitated drinking, and that subsequent decrements in drinking presumably reflected the loss of some stimuli which were reinforcer-linked CSs. Since there were no changes in the burette used for the tube-drinking response, or in its location, the rats presumably "knew" where the water spout was. (A possibility which does require further analysis is that the changes in stimulation produced so-called novelty reactions which interfered with drinking.)

Note that associative influences on consummatory measures may mask some of the effects of degree of deprivation. For example, in the experiment of Stellar and Hill (1952), each rat's water intake was measured in the individual home cage under all the deprivations. Moreover, each rat had been housed, fed, and watered there

for a month before the deprivations were initiated. At the end of a month, interference with drinking by novelty reactions should have been negligible, and the acquired effects of water-linked conditioned stimuli in the experiment should have been strong enough to facilitate prompt and persistent drinking, at least during the initial minutes of the 2-hour test; this would tend to reduce any differences in 5-minute water intakes among the various deprivation times, since species such as rats cannot drink enough in 5 minutes to correct their water deficit completely. We should also note Collier's (1964) point that when the 2-hour water intake data of Stellar and Hill are replotted on log-log coordinates, the intake is linearly related to the deprivation time. Apparently a 2-hour water intake measure is meaningfully related to the degree of deprivation whereas the 5-minute intakes may be distorted to some extent by associative influences.

Up to this point we have considered evidence for two principal kinds of associative effects on consummatory activities that may be attributed to *external* stimuli in the test situation. First, performance of the consummatory response in the test situation permits external stimuli to become reinforcer-linked CSs. Later, these CSs may tend to elicit the consummatory response or to facilitate or enhance the subsequent occurrence of the consummatory response. Second, even in the absence of the consummatory response, exposure to the test situation may result in a decrement in novelty reactions as the situation becomes more familiar, and subsequently there may be less interference with the consummatory response.

We can now recapitulate the reasons for the view that so-called "adaptation" to periodic deprivations does *not* provide unambiguous evidence that *internal* deprivation stimuli (S_{MV}s) have acquired some degree of associative control of behavior. When rats have been maintained on a 22- or 23-hr food-deprivation schedule, it has been found that food intake usually increases across days.

Although it is clearly a digression from our main question, we will cite several studies on "adaptation" to deprivation schedules because they have practical implications for the design of experiments wherein drive is alleged to be constant when the deprivation times are constant. Certain studies report that it may take about two weeks for the rat's food intake and body weight to stabilize on a 23-hr food-deprivation schedule (Lawrence & Mason, 1955b; Reid & Finger, 1955; Dufort, 1964b). Apparently the rat fails to stabilize its body weight when it is maintained on 47- or 71-hr food-deprivation schedules (Dufort, 1964b).

In the case of water deprivation, rats maintained on 23-, 47-, and 71- hr deprivations have, after initial weight losses of varying severity, reached a point where their weight was relatively constant (Dufort, 1963a, 1964a). Beck (1962) found that when the days of water deprivation were separated by recovery days, increments in drinking across deprivation cycles did not occur. He attributed the absence of the increased water intake across deprivation cycles to the absence of a cumulative water deficit. Reid and Finger (1955) noted that, contrary to the constancy of drive level that has been assumed for 23 hr of food deprivation, the daily variations in body weight deficit before body weight is stabilized presumably reveal daily variations in the strength of drive. Ehrenfreund (1960) described a weight control apparatus whereby the rat's food supply is precisely regulated by the rat's weight. In this way one can maintain constant the percentage weight deficit, and presumably the amount of drive due to food deprivation. Due to shifting cumulative weight deficits and the acquired associative effects of external stimuli, the cited studies of "adaptation" to deprivation schedules cannot be interpreted unequivocally as evidence that the rat is learning to discriminate the presence or degree of deprivation, or that learning is occurring in the form of the internal deprivation stimuli (S_{MV}s) becoming associated with eating.

Sometimes increments in food and/or water intake have been interpreted as evidence that the rat learned to associate *internal* deprivation stimuli with consummatory responses which terminate the deprivation (S_{MV}s became CSs for consummatory responses). We have emphasized that the unequivocal interpretation of such studies has been hindered by at least three confounding variables, and we have presented evidence that these three variables influence consummatory responses. These factors are, first, when rats are maintained on a 23-hr food-

deprivation schedule for several days, the presence of an increasing cumulative weight deficit can preclude the unequivocal interpretation of any alleged signs of learning to eat promptly, persistently, and larger quantities of food. Other complications are that, with repeated feedings in the test situation, the effects of *external* stimuli can confound tests of the alleged effects of hypothesized *internal* deprivation or satiation stimuli (for example, external stimuli associated with food and eating may become reinforcer-linked CSs which enhance eating, and decrements in novelty reactions to external stimuli may result in more eating).

After adaptation to one feeding a day, rats eat *less* if tested after deprivation periods longer than 24 hr (Bousfield & Elliot, 1934; Lawrence & Mason, 1955a). But they also eat less at 47 and 71 hr of deprivation the first time they are exposed to such treatment (Dufort, 1964b). On the other hand, if the animals are exposed to deprivations that are varied randomly between 4 and 48 hr, a higher food intake at the longer interval will be maintained (Figure 18.9). Apparently it is adaptation to a once-a-day feeding and its relation to the daily rhythms of the organism that makes the intake at 24 hr greater than at other deprivation intervals (see Bolles & deLorge, 1962; Bolles & Stokes, 1965).

Figure 18.9. Three-hour food intake as a function of hours of food deprivation. Periodic Group (solid curve) had been maintained on a regular 24-hr feeding schedule and its food intake decreased in tests which followed deprivations in excess of 24 hr. Aperiodic Group (dot-dash curve) had been exposed to deprivations of 4 to 48 hr, in random sequences, and its food intake remained essentially constant on test trials after deprivations between 24 and 48 hr. (Modified from Lawrence & Mason, 1955a.)

Moll's (1964) experiment, with cumulative percentage weight deficits effectively controlled, demonstrated reliable practice effects. Rats of three age groups (33, 63, and 93 days) were maintained at a constant percentage of their satiated weight, derived from estimations of anticipated growth. Half of the subjects were maintained at 80 and the other half at 90 percent normal body weight. Practice over 15 days in a new situation had highly significant over-all effects resulting in shorter latencies to eat, more time spent eating, larger amounts eaten, and faster eating rates in a 5-min test. Since the percentage body weight deficit was held constant, this study appears to provide excellent support for the hypothesis that measures of consummatory activity can show improvement with practice which cannot be attributed to an increasing percentage weight deficit. Again, these data do not prove that *internal* deprivation stimuli became increasingly associated with eating: it is also possible that *external* stimuli developed progressively as reinforcer-linked CSs which elicited or facilitated eating, and decrements in novelty reactions to external stimuli may have permitted increments in measures of eating.

Recently, the study of Williams (1968) provides additional evidence that food intake increases with practice in a new test situation in the absence of a rising cumulative percentage weight deficit. In her first experiment, rats were food-deprived for 21 hours on every fifth day for a series of seven completed cycles. *Ad libitum* food was available the rest of the time and water was always available in the home cage. The subjects were normally fed Purina laboratory pellets in the home cage and they were tested with sweetened milk

in a test cage. More milk was consumed during the 3-hour test period on deprived than on nondeprived control days. Moreover, a practice effect was observed: intake of sweetened milk during the 3-hour test period increased across days for both the deprived and nondeprived conditions considered separately. In Williams' (1968) second experiment, the time in the test cage was reduced to two hours, so in this case the deprivation every fifth day was 22 hours. Fourteen deprivation cycles were employed, which extended a little over two months. The 2-hour intakes of sweetened milk increased across days for both the deprived rats and the nondeprived control subjects, but, as expected, the deprived rats had a larger milk intake than controls.

"GENERAL ACTIVITY" AS AN INDEX OF DRIVE

Concept and Measurement of "General Activity"

The effects of deprivation states on "general activity" were studied before the development of formal drive theory. It seemed reasonable, from a common-sense point of view, that increased behavioral activity due to hunger would have survival value and help to perpetuate the species because, in a natural environment, heightened activity would supposedly increase the chances that a hungry animal would find food. Accordingly, mechanisms might have been inherited whereby food deprivation per se would be expected to enhance locomotion and exploratory activities.

Alternatively, one might assume that strong internal and external stimuli have similar drive properties, and that these evoke vigorous activity, so that during starvation strong internal deprivation stimuli would innately evoke vigorous activity (see Miller & Dollard, 1941; Miller, 1959).

All of us have observed that most organisms seem to be engaged in a continuous sequence or stream of behavioral activities. Many of these activities are species-specific activities, and ethologists have emphasized the desirability of becoming familiar with the complete repertoire of "naturally" or "normally" occurring behavioral activities of a species.

It is obviously important for experimental psychologists to consider the extent to which recording techniques may influence or modify the behavioral activities being studied. One must also consider whether the observational technique accurately represents the behavioral activities or whether, in some incompletely specified way, the recording device emphasizes some behavioral activities at the expense of neglecting others. The design of suitable devices to record a wide assortment of activities, in other words, involves serious methodological problems if one is to avoid a completely arbitrary or capricious assignment of importance to different individual acts.

Several different designs of stabilimeters have permitted automatic recording of behavioral activities of freely moving animals (Reed, 1947; Munn, 1950; Baumeister, Hawkins, & Cromwell, 1964). The total activity recorded in this way might be unchanged at times when important changes in the patterns of activity have occurred, and there may be artifactual changes in apparent activity level because recording devices can more readily detect and record some activities than others. For these reasons, the expression "random activity" appears to be a misnomer in the sense that, if used descriptively, it implies that the behavioral activities are occurring in random sequences, a factual question for which the usual tracings or counts of stabilimeter activity have not provided objective answers. Similarly, if "general activity" is interpreted in a literal descriptive sense, one would expect different "valid" measures of general activity to be positively and significantly intercorrelated; this has not been the case (Reed, 1947; Baumeister et al., 1964). For example, Bolles (1959) tested adult male rats in six different situations (open-field apparatus, feeding-drinking box, elevated runway, alley runway, home cages, and stabilimeter cages) and found that correlations and other analyses revealed a lack of generality across situations (see also Campbell et al., 1966; and review by Reed,

1947). What seem to be needed, at this point, are careful detailed analyses of the specific components of "general activity" (Bindra, 1961; Hinde, 1966).

Associative Influences on Activity Measures

External stimuli "evoke" stabilimeter activity Campbell and Sheffield (1953) tested the effects of food deprivation on stabilimeter activity under conditions designed to minimize variations in environmental stimuli. The cages were in a soundproofed cabinet within a soundproofed room and in the dark except when lights within the cabinet were turned on. A controlled 10-minute stimulus change was introduced at noon which consisted of turning the cabinet lights on and the exhaust fan, with its continual hum, off. Stabilimeter activity was significantly higher during the period of changed stimulation than during the preceding 10 min. This effect was reliably present before food deprivation was initiated; when continuous food deprivation was initiated, the 10-min activity scores during altered stimulation increased across 3 days, while the activity scores during the 10-min period preceding the stimulus change were apparently unaffected by the presence or absence of food deprivation. In other words, experimentally controlled changes in external stimulation produced large and significant changes in stabilimeter activity of food-sated rats, and this effect was markedly enhanced by food deprivation, but there was little evidence that food deprivation per se caused increased activity.

More recent experiments (for example, Teghtsoonian & Campbell, 1960) also seem to indicate that any effect internal deprivation stimuli may have in goading adult rats into activity is at most a minor one and probably not even detectable in a controlled stabilimeter environment until there has been extended and continuous food deprivation.

Campbell, Teghtsoonian, and Williams (1961) studied the effects of continuous food deprivation on rats of four age groups: 23, 38, 54, and 100 days old at the start of the experiment. Stabilimeter activity increased markedly for the younger rats (23, 38, and 54 days old) but scarcely at all for 100-day rats.

In a parallel experiment with continuous water deprivation (Campbell & Cicala, 1962), at no time was there any appreciable increase in stabilimeter activity. On the basis of such observations, we are led to discount any theory which assumes that organismic needs lead directly to increased activity. Furthermore, if the concepts of general drive and drive stimuli are to be applied meaningfully, some explanation is required for the different effects of food and water deprivation on the stabilimeter activity of young rats.

External stimuli: reinforcer-linked CS effects on stabilimeter activity The amount of stabilimeter activity of hungry rats that occurs in response to environmental change depends on whether the environmental change and stabilimeter activity are paired with *food* (Sheffield & Campbell, 1954). For experimental subjects, a 5-min stimulus change was followed by presentation of the daily food ration; their total activity for the 5-min stimulus-change period increased across daily trials (as in the so-called conventional learning curve). For control subjects, the termination of the 5-min stimulus change was not immediately followed by the presentation of food, and their total activity for the 5-min stimulus-change period decreased over the 12 days studied. Thus food deprivation interacted with stimulus conditions and reinforcement contingencies to increase stabilimeter activity markedly for the experimental group and to decrease it for the control group.

In extensions of the Sheffield and Campbell (1954) experiment, Amsel and Work (1961) and Amsel, Work, and Pennick (1962) included additional groups which were fed on only half of the stimulus-change trials in order to permit observation of the development of any effects attributable to frustrative nonfeeding. They confirmed the main findings of Sheffield and Campbell (1954), and also found some activity increments associated with nonfeeding when it was intro-

duced after extensive prior experience with a food-paired stimulus.

Although Bindra and Palfai (1967) did not study stabilimeter activity, their inclusion here may serve to clarify some of the reinforcer-linked CS effects on behavior, including stabilimeter activity measures. They placed water-deprived rats in a restraining cage, and during the conditioning procedure, a 15-min auditory CS+ was paired with water delivery during the terminal 1 second of the CS+; a CS− was paired with electric shock applied through electrodes attached to the hind limbs, and CS_0 was not paired with either shock or water. Subsequent tests revealed that CS+ increased "exploratory perambulation" and the CS− increased "motionless sitting," relative to control conditions. In part because specific responses which compose "exploratory perambulation" could not have been conditioned in the restraining cage, they suggested that the reinforcer-linked conditioned stimuli induce positive and negative drive states which (p. 297) ". . . raise the level of motor readiness, presumably by increasing the excitability of the response system."

Further observations on the "threshold of behavioral arousal" have been provided by Bolles and Younger (1967), who presented a series of ascending intensities of "high frequency white noise" to individually-housed rats, while an observer recorded which subjects responded to it. Startle, disruption of on-going behavior, and orienting or exploratory behavior were all simply scored as a response. In one of their experiments, median thresholds (derived from the decibel level of auditory stimulation required for behavioral arousal) were not reliably different between 8 nondeprived controls and 8 experimental subjects during 7 days of continuous food deprivation which resulted in a weight deficit of 30 percent or more. In another experiment, control and experimental subjects differed only before a regularly scheduled feeding, when food-deprived subjects had reliably lower thresholds for behavioral arousal (that is, weaker auditory stimuli were effective). These data, therefore, do not support any hypotheses that food deprivation is in itself sufficient to lower sensory or response thresholds. However, 30 min before a regularly scheduled feeding and presumably in the presence of incentive motivation (that is, food-linked CS effects), weaker auditory stimuli were more effective in eliciting behavioral arousal in experimental subjects with a slight weight deficit than in controls fed *ad libitum*. Since the half-second test noise had not been paired with food, it would appear that in the presence of incentive motivation rats were more responsive even to a "neutral" test noise of low intensity.

Running in activity wheels This activity measure has been found to vary with the severity of food deprivation, at least for rats, hamsters, and guinea pigs. Before we attempt to evaluate the significance of such data for the concept of drive as a general energizer, we will first consider several possible sources of reinforcement which apparently influence the running of rats in activity wheels.

Finger, Reid, and Weasner (1960) investigated the effects of food as a reinforcer on running in an activity wheel. Controls were in the activity wheel for an hour, and then were placed in a delay chamber for an hour without food or water; their running did not reveal any systematic trend across 30 test days. Experimental rats were taken from the activity wheel and returned at once to their home cages and food. The experimental group showed an approximately fourfold increase in 1-hr running scores across the 30 test days. Clearly, if running in an activity wheel is followed by food, there is enhancement of running.

It should also be recalled (see pp. 623–624) that running in an activity wheel can serve to reinforce other instrumental and consummatory responses (Premack, 1962, 1965), and vice versa. Such effects may greatly confound experiments using activity wheels, and at the very least, they indicate that running cannot

be used as an uncomplicated index of deprivation.

Thermo-regulatory mechanisms have been implicated as a possible source of reinforcement for running in activity wheels during starvation. Stevenson and Rixon (1957) proposed that running in the activity wheel involves vigorous skeletal activity which in food-deprived rats contributes to maintaining body temperature. They found that running in activity wheels was greater in food-deprived than sated rats, and that the extent to which activity scores were enhanced by food deprivation was inversely proportional to the environmental temperature.

Campbell and Lynch (1968) made continuous subdermal temperature recordings while rats were in either stabilimeter or modified activity-wheel cages, under *ad libitum* feeding or food or water deprivation. When observed in the activity-wheel cages, body temperatures decreased sooner during food than during water deprivation. Conversely, in stabilimeters, body temperatures dropped (contrary to Stevenson & Rixon, 1957) sooner and more during water than during food deprivation. Activity in the wheel and in the stabilimeter increased more markedly during hunger than during thirst. In another experiment, running in cool activity wheels increased quite similarly during food or water deprivation, even though an adjacent heated compartment was readily accessable through small swinging doors. In spite of the very similar running scores, time spent in the heated compartment increased markedly throughout terminal food deprivation but it decreased during terminal water deprivation. In agreement with these results is the finding reported by Smith, Satinoff, and Rozin (1967) that, relative to controls, food-deprived rats still ran more in activity wheels even when they were able to obtain warmth easily by pressing a bar. Such results indicate clearly that the rat's increased running in activity wheels as a function of food deprivation cannot be attributed solely to the need to raise body temperatures to a normal level.

Activity Measures as a Function of Deprivation

Most of the data on running in activity wheels as a function of body-weight deficits appear to be consistent with the view that, for rats at least, running is the dominant response in the activity wheel and that running scores increase as a function of body-weight deficit because the dominant response is being increasingly energized as the drive level rises. Inanition is not a helpful concept in this context, over most of the useful working range of degrees of food and water deprivations for rats as subjects. In stabilimeter-type apparatuses, on the other hand, when variations in external stimuli are minimized, food- or water-deprived rats are performing passive forms of behavior (such as lying) most of the time, and these do not contribute to raising stabilimeter activity levels. More importantly for drive theory, there are few active responses to be increasingly energized as deprivation progresses and drive allegedly rises. Such gross apparatus effects must be kept in mind when deprivation effects are discussed.

Inherited individual and species differences in activity Rundquist (1933) used activity wheel scores to identify active and inactive rats, and by selective breeding successfully separated and maintained active and inactive strains.

Campbell, Smith, Misanin, and Jaynes (1966) studied stabilimeter activity during continuous deprivation (either food or water) of chicks, rabbits, guinea pigs, and hamsters; they also studied the effects of continuous deprivation (either food or water) on running in activity wheels by guinea pigs and hamsters. Their results reveal marked differences attributable to differences in measuring devices (stabilimeter versus activity wheel), type of deprivation (food or water), species, and perhaps age. Such data pose serious difficulties for anyone who still maintains that deprivations produce generalized drive which necessarily increases "general activity" (see also DeVito & Smith, 1959; Glickman & Hartz, 1964).

Estrus and activity cycles If sexual hormones are considered to determine the amount of drive of sexual origin, then the

estrus cycles of mature female rats should be accompanied by corresponding cyclical variations in drive. Wang (1923) found that, in the absence of male rats, the amount of running in the activity wheel did vary cyclically in close correspondence with the estrus cycles. Such cycles in amount of running in activity wheels were absent in female rats before sexual maturity and after ovariectomy. Finger (1961) found similar cyclical variations in activity; he measured running in activity wheels and the number of interruptions of a light beam in a stationary cage. Although the periodicities of these activity cycles were of the same magnitude as estrus cycles, apparently tests for consistent phase relations between the estrus and activity cycles were not made. Bolles (1963a) used sexual receptivity to determine cycle phase, and a time-sampling procedure to observe home-cage behavior, which was classified in one of these categories: "sleeping, lying, grooming, sniffing, eating, drinking, locomotion, rearing, or manipulating objects." There was no correlation between these activity scores and sexual receptivity. We are therefore left with the conclusion that estrus does not increase behavior in an indiscriminate manner, as sometimes seems to have been implied by earlier writers.

Over-all Conclusions on "General Activity" as an Index of Drive

Our primary objective has been to see whether studies of so-called "general activity" reveal any consistent relation between activity measures and degree of deprivation, because this could tell us how drive varies with degree of deprivation. Hullian drive theory specifies that, over an extended range of deprivation times, effective drive (that is, drive minus inanition) should be a curvilinear or inverted-U function of deprivation times. Thus a dominant response measure energized by effective drive should tend to be curvilinearly related to deprivation times as well.

An explicit estimate of how inanition varies with deprivation time has been made for rats by Yamaguchi (1951); inanition reportedly increases exponentially with deprivation time so that the resultant effective drive increases during food deprivation up to about 60 hours and thereafter effective drive decreases as food deprivation continues.

Data on running in activity wheels indicate clearly that rats increase the amount of running progressively and monotonically during continued starvation, up to a very severe degree of deprivation. This may be an indication that, for adult rats, there is no appreciable inanition during relatively prolonged continuous food deprivation. It could also mean that rats can respond vigorously in spite of inanition, and this would account for the fact that during starvation rats succumb sooner in activity wheels than in stabilimeter cages. If the latter hypothesis were correct, we would have to know when, and under what conditions, the hypothesized inanition will be reflected in behavior. Obviously inanition should not be invoked in a post hoc manner only to "explain" curvilinear relations between behavioral measures and degree of deprivation, without explaining as well how it is that some responses increase monotonically over the same range of deprivations.

Another problem for a drive interpretation of functional relations between activity measures and degree of deprivation is that the effects of drive may be confounded by the effects of drive stimuli as continuous food or water deprivation progresses. It appears one can safely conclude that for adult rats, in the absence of food and food-linked CSs, internal drive stimuli defined in relation to deprivation time do not readily acquire associative "control" of running in activity wheels, nor of whatever responses are being recorded in stabilimeters.

With regard to the question whether internal drive stimuli instigate activity, the acceptance or rejection of this hypothesis appears to depend on an individual's theoretical bias as to what will be the most fruitful way of viewing and integrating data from various experiments. Nowadays, the more significant problem appears to be one of understanding the different patterns of activity that result from differences in age, species, type of deprivation (food or water), and apparatus (stabilimeter or activity wheel). These differences

in results are not easily reconcilable with assigning an important role to internal drive stimuli as instigators of activity in young subjects.

Finally, the available data on "general activity" do not demonstrate unequivocally *the* rate of increase of effective drive as a function of deprivation times or body weight deficits, nor do these data reveal unambiguously over what range of deprivation times or weight deficits effective drive can be assumed to increase.

INSTRUMENTAL ACTIVITY AS A FUNCTION OF DEPRIVATION

Deprivation Effects on Instrumental Responses During Extinction

Analysis of the effect of food deprivation time on an instrumental response during the extinction procedure would appear to be of special interest because food no longer follows the instrumental response. The results obtained are not likely to represent a pure deprivation effect, however, because the associative strength of the incentive motivation (food-linked CS effects) acquired on the previously reinforced trials presumably is present at the start of the extinction procedure and supposedly decreases progressively at some unknown rate during extinction. Moreover, if a response has been reinforced on a continuous reinforcement schedule (for example, with each bar press reinforced with a pellet of food), and if this is followed by the extinction procedure, we may have satisfied the conditions for frustrative nonreinforcement, which some view as a source of a general energizer.

Degree of food deprivation has a significant over-all effect on the persistence of instrumental responding during the extinction procedure. For example, Perin (1942) trained rats to press a bar by reinforcing each of 16 bar presses with one pellet of food. This training took place at 23 hr of food deprivation. After the next daily feeding, extinction tests were conducted. Resistance to extinction was tested at 1, 3, 16, and 23 hr of food deprivation, with a separate group of 40 subjects for each deprivation state. Number of responses to meet the extinction criterion (no responses within a 5-min period) was an increasing monotonic function of hours of food deprivation. Hull's (1943) formulation, which relates behavior to ${}_SH_R \times D$, was in part based on these data. It is also true, however, that resistance to extinction was greatest when the hours of deprivation were the same during training and extinction (that is, 23 hr), and progressively less as the deprivation during extinction became increasingly different from that during training. Thus the results might, at least in part, be attributed to the response decrement expected from a generalization gradient.

Saltzman and Koch (1948) explored the range of low intensities of food deprivation and concluded that resistance to extinction dropped off more rapidly than predicted from extrapolation of Perin's (1942) results. Yamaguchi (1951) investigated deprivation times up to 72 hr, and found that increments in food deprivation beyond 24 hr had little if any additional effect on resistance to extinction.

Deprivation Effects on Reinforced Instrumental Responses

Heron and Skinner (1937) observed the number of bar presses in daily 1-hour tests where only the first response after every fourth minute was reinforced with food. This provided a daily food ration of about 0.7 grams of Purina dog chow (water was always available). On the average, rate of bar pressing increased in an approximately linear fashion during the initial 5 days of deprivation, and then decreased slightly on the sixth day. However, the peak rate of bar pressing occurred as late as on the eleventh day of testing for 2 rats and on the thirteenth day for 1 rat.

Stolurow (1951) found that rats kept at 70 percent of their *ad libitum* body weights penetrated a barrier to obtain food faster than a group kept at 80 percent of their *ad libitum* weights. A shift of body weight from 80 to 70
Figure 18.10. These curves illustrate the lack of agreement among 4 potential response indices of hunger as a function of hours of food deprivation. The *z* or standard scores were "derived from the average within-test-condition variability" for the 6, 30, and 54 hr of deprivation. Maximal mean differences within any response measure between 6 and 54 hr of deprivation were less than 2 standard deviations. Bar pressing (●—●) on a variable-interval reinforcement schedule and amount of quinine (●--●) adulteration required to stop drinking milk increased monotonically up to 54 hr deprivation; stomach contractions (○—○) changed very little between 6 and 54 hr; drinking milk (○---○) increased slightly from 6 to 30 and decreased from 30 to 54 hr deprivation. (Modified from Miller, 1956.)

percent was accompanied by a significant improvement in performance on the barrier penetration test. However, rats tested at 60 percent body weight tended to resemble more closely 80 percent body weight group than the 70 percent group. There is a suggestion, therefore, that performance on the barrier penetration test was optimal at 70 percent of *ad libitum* body weights.

Miller (1956) has compared various consummatory and instrumental activities as measures of so-called hunger (Figure 18.10), and they clearly diverge from each other to some extent. Bar pressing for food on a variable-interval reinforcement schedule apparently increased monotonically up to 54 hr of food deprivation in an intrasubject comparison.

Data on running in mazes and activity wheels are somewhat similar, for rats at least, in the sense that amount of running per unit time tends to increase with deprivation times (food or water) for the initial 72 hr. King (1959, cited by Kimble, 1961) found that the mean time required to traverse a runway decreased monotonically for food deprivations of 2, 24, 48, and 72 hr respectively (independent groups of rats tested at each deprivation). The results were essentially similar regardless of whether or not competing responses were included for deprivations of 24 to 72 hr (see Figure 13.5 in Kimble, 1961). Granger, Ducharme, and Bélanger (1969) have likewise found that runway speeds increased during water deprivation, without any signs of a decrement in speed for continuous deprivations up to 72 hr.

In marked contrast to the above results, bar pressing has been found to be curvilinearly related to the duration of continuous
Figure 18.11. Number of bar presses for water on a continuous reinforcement schedule in a 5-min test as a function of the hours of water deprivation. Each rat was tested at each deprivation in an ascending order. (Bélanger & Feldman, 1962).

deprivation when every bar press is reinforced ("continuous reinforcement" or crf schedule).

> Bélanger and his colleagues have performed a series of studies designed to investigate systematically the effects of a wide range of deprivation intensities on bar pressing on a crf schedule. In order to ensure a steady rate of responding Bélanger and Feldman (1962) began with a 20-day training period in which 24-hr water-deprived rats bar pressed for water on a crf schedule. Next, prior to the main part of their experiment, they tested the rats under several different durations of a continuous water deprivation so as to provide the rats with exposure to varying degrees of water deprivation, and with the opportunity to adapt to the deprivation and testing procedures. Throughout the experiment, the subjects had free access to water for three or four days after every deprivation condition in order to prevent any cumulative deficits over the series of deprivations. Rate of bar pressing for water was a curvilinear function of hours of water deprivation; the average peak rate of bar pressing occurred at 48 hours of water deprivation (Figure 18.11).

In a similar study with different durations of continuous food deprivation (0, 6, 12, 18, 24, 36, and 48 hr), rate of bar pressing for food on a crf schedule was also found to be a reliable curvilinear function of deprivation times (Dufresne, 1961). The peak rate occurred at 18 hr of food deprivation, which is much sooner than with water deprivation. These data indicate clearly that even with performance of the seemingly simple instrumental response of bar pressing for an appropriate reinforcer on a crf schedule, performance is not a monotonic function of hours of deprivation.

Does the decrease in response rate at the higher deprivation levels indicate inanition? To test this hypothesis, rats were adapted and trained (as in the Bélanger & Feldman experiment) to bar press for water under 23 hr water deprivation. Then they were given an electrical shock immediately before being placed into the Skinner box (Ducharme & Bélanger, 1961). When given in this way, the electrical shock may be expected to raise the drive level without there being any opportunity for the electrical shock itself, as a stimulus, to become associated with stimulus features in the Skinner box. In other words, the use of shock before placement into the Skinner box was intended to prevent any stimuli within the Skinner box from acquiring conditioned aversive properties because of the shock. Intra-individual comparisons were made for several different shock intensities. A single shock was given each day, and the seven intensities of shock were given in an ascending series over seven days. Rate of bar pressing for water on a crf schedule was a curvilinear function of shock intensity, and reliably different from any possible linear fit (Figure 18.12). In this case, the rats were deprived of water for only 23 hr, and inanition appears to be effectively ruled out. These data are also relevant to the question of how an instrumental response is influenced by the alleged summation of generalized drive from

Figure 18.12. Mean number of bar presses for water on a continuous reinforcement schedule in a 6-min test as a function of prior shock intensity in milliamperes. Each rat was water deprived for 23 hr and tested at each shock intensity in an ascending order, given one shock per day on separate days. (Modified from Ducharme & Bélanger, 1961.)

multiple sources. A weak shock should elevate the drive level slightly, and on the basis of Figure 18.11 it is reasonable to predict that, at 23-hr water deprivation, a prior weak shock would raise the rate of bar pressing for water, as it did (Figure 18.12). Similarly, on the basis of Figure 18.11, we can see how a strong shock would raise the combined drive level at 23-hr water deprivation in excess of the optimal level, and rate of bar pressing for water would decrease, as it did (Figure 18.12). These effects of shock (that is, the reliable curvilinear function between shock intensity and rate of bar pressing for water) cannot be accounted for by merely assuming that shock as an aversive stimulus tended to elicit responses incompatible with bar pressing for water. Ducharme and Bélanger (1961) predicted their result from the hypothesis that there is an optimal level of drive or arousal for this instrumental response.

In a second experiment, rats did not show the decrement in rate of bar pressing for food between 24 and 60 hr of food deprivation when they were given meprobamate, a relaxant of the skeletal musculature (Figure 18.13); a control group, given a placebo, essentially replicated the earlier finding of a decrement in rate of bar pressing for food between 24 and 60 hr of food deprivation. The superior performance with meprobamate appears to rule out inanition as the essential cause of a response decrement during 24-60 hr of food deprivation.

Figure 18.13. Effect of meprobamate on the mean number of bar presses for food on a continuous reinforcement schedule in a 5-min test as a function of hours of food deprivation. A significant response decrement between 24 and 60 hr of food deprivation was present in placebo-treated controls (dashed line) and in untreated controls (not shown here), but not in the meprobamate-treated experimental subjects (solid line). (Modified from Dufresne, 1961.)

Another feature of this series of experiments is especially relevant to an assessment of reinforcer-linked CS effects on instrumental activity. For this reason we will refer briefly, at this point, to some data on heart rate as an indicant of arousal level. It has been found that the function between heart rate and hours of deprivation apparently depends on situational cues (Ducharme, 1966b). In Figure 18.16, we see that for experimental subjects trained to bar press for water, heart rate was linearly related to hours of water deprivation (up to 72 hr) while they were bar pressing for water. An approximately similar monotonic function between heart rate and deprivation time was obtained for these trained subjects in their home cage, but their heart rates were reliably lower (the attachment of recording electrodes in the home cage may have provided some stimuli which in the Skinner box had become water-linked CSs). Controls were not trained to bar press for water and their heart rates were unrelated to hours of water deprivation, up to 72 hr. In other words, heart rate as an indicant of arousal level did not automatically increase with degree of deprivation; instead, the effect of deprivation depended on an interaction between deprivation and appropriate cues. (that is, water-linked CSs).

Some of the relations observed between instrumental responses and degree of deprivation have been curvilinear functions, which would be predicted from the so-called "Yerkes-Dodson Law." Yerkes and Dodson (1908) varied both difficulty of a brightness discrimination and intensity of shock used to punish incorrect responses. Their results are consistent with the view that as the difficulty of the discrimination increased, the optimal shock intensity for acqui-

sition of the discrimination approached a lower limiting value. It has been claimed (for example, Brown, 1965) that other interpretations of these data are possible for a variety of reasons, but especially because a factorial design was not used and there were too few subjects (2 to 4 mice) per group.

Broadhurst (1957) provided further evidence that task difficulty is one of the parameters to consider when studying the relation between discrimination learning and drive level. Rats were deprived of air for varying durations and then forced to swim underwater. Next, rats were trained to make a brightness discrimination in order to obtain access to air. Separate groups were tested at 0, 2, 4, and 8 sec of air deprivation. In the acquisition of the brightness discrimination, there was a reliable interaction between air deprivation time and difficulty of the brightness discrimination for accuracy. Performance on the difficult brightness discrimination showed best acquisition at 2 sec and poorest acquisition at 8 sec air deprivation, whereas the easy and moderately difficult discriminations were poorest at 0 sec and generally equally superior throughout 2 to 8 sec of air deprivation. These data, therefore, provide evidence for an optimal duration of air deprivation during the acquisition of a difficult discrimination, but there is no statistically adequate evidence in these data for an optimal drive level for acquisition of discriminations of easy or moderate difficulty. At present, the "Yerkes-Dodson Law" remains a plausible but relatively unexplored generalization.

Associative Effects of Internal Deprivation Stimuli on Instrumental Responses

To the extent that instrumental responses become associated with specific internal deprivation stimuli, any shift in degree of deprivation should produce at least a slightly different set of internal deprivation stimuli and, therefore, a response decrement due to the generalization gradient. Thus any response decrement produced by a shift from a higher to a lower deprivation level may theoretically be attributable to a lower drive level and/or a shift in drive stimuli. However, a shift from a lower to a higher deprivation level would theoretically have two opposing potential effects: increased drive should energize the instrumental response to a greater extent and make it stronger, whereas a shift in deprivational stimuli should produce a response decrement. The study of Hillman, Hunter, and Kimble (1953), referred to earlier in our illustrations of motivational effects, provides an example of data which are in accord with an emphasis on the drive concept: a change from 2 to 22 hr of water deprivation resulted in running times within two trials as short as those for rats maintained on 22 hr deprivation throughout the experiment (Figure 18.1).

In one of the most extensive studies of this topic, Yamaguchi (1952) trained rats to move a manipulandum leftward for food. A shutter made the manipulandum accessible only in discrete trials and a response latency was measured. In a factorial design, 5 groups of rats (195 in all) were trained at 3, 12, 24, 48, or 72 hr and tested at 3, 24, 48, or 72 hr of food deprivation. For the most part, the group differences in median latencies were relatively small. However, a shift in deprivation time from training to testing resulted in a response decrement (that is, longer median latency) in 14 out of 15 comparisons of group medians, when comparisons were made among groups tested at the same deprivation time (and therefore the effects of drive stimuli were never obscured by any test effects attributable to increased energization by heightened drive).

These results thus suggest that there may be associative effects attributable to internal deprivation stimuli, but at best the effect appears to be small.

Although Birch, Burnstein, and Clark (1958), with a single group of subjects, observed generalization decrements in food-trough depression responses when continuous food-deprivation extended beyond the hours of deprivation used during training, this result is most likely due to the food-trough responses undergoing extinction. Brown and Belloni (1963) tested separate groups at 5 different deprivation times and they found no evidence of generalization decrements in food-trough responses for continuous deprivation times in excess of the training depri-

vation time of 22 hr. They were also unable to replicate the finding by Birch et al. (1958) of generalization decrements in running speeds, although both studies employed separate groups at different deprivation times to test for this effect. Bolles (1961) found generalization decrements following maintenance on a 24-hr diurnal feeding schedule, but not for a 29-hr a-diurnal schedule. Significantly fewer bar presses for food were observed in tests at 19 and 29 than at 24 hr of food deprivation for rats trained and maintained on the 24-hr feeding schedule. Another group, trained and maintained on the a-diurnal 29-hr feeding schedule, had the largest number of bar presses at 34 hr, and fewer bar presses at 29 than at 24 hr of food deprivation.

Thus the various studies we have considered on generalization decrements attributable to shifts in hypothetical internal deprivation stimuli have revealed that a shift in duration of deprivation from training to test trials has typically resulted in either no significant generalization decrements, or in decrements of relatively small magnitudes. When other than 24-hr diurnal cycles are used during training and maintenance, it has been especially difficult to identify any experimental situation that can yield replicable evidence for generalization decrements. It therefore would seem that considerable reservations are in order concerning any theory which assigns *major* importance to alleged associative effects of hypothetical internal deprivation and satiation stimuli.

AROUSAL LEVEL = GENERAL DRIVE?

Concept and Measurement of Arousal

For at least three decades several kinds of physiological data appeared to be suggestive of a factor that has been variously called degree of excitation, energy mobilization, activation, and arousal. These terms have at times been used interchangeably; they generally refer to measures that in varying degrees may be indicative of the organism's overall level of physiological activation or excitation. Some of the physiological data that led to arousal-type formulations consisted of recordings of autonomic activity and skeletal muscle tension (in the form of electromyographic, or EMG, potentials) in experiments with human subjects (see, for example, Lindsley, 1951; Woodworth & Schlosberg, 1954; Malmo, 1958; Duffy, 1962).

Electroencephalograms (EEGs) have provided an important part of the data relevant to arousal theories; these data are recordings of electroencephalic potentials ("brain waves") from the scalp and from the exposed cortex. (In recent years, electrical recordings have been used extensively to study subcortical areas of the brain as well.) A frequently used index of arousal is the amplitude of the alpha rhythm (approximately 10 Hz), which is maximal in the relaxed, awake human adult with eyes closed, but whose amplitude and incidence both decrease if the subject *either* becomes excited (when lower amplitude, faster rhythms predominate) or becomes drowsy (when lower amplitude, slightly slower rhythms may temporarily predominate, to be followed by slower waves of higher amplitude as the subject falls asleep). Since the EEGs from different cortical areas usually can be categorized within the same stage of sleep-wakefulness, this suggests that there is some diffusely acting mechanism which serves to maintain the cortex as a whole at the relatively same over-all level of excitation.

Pivotal importance of general activation In the late 1940s neurophysiological research seemed to reveal brain structures capable of functioning as a general activating mechanism. Lindsley (1951) proposed an activation theory of emotion which was highly influential in suggesting to many psychologists that the then contemporary neurophysiological research on diffusely activating mechanisms in the central nervous system was highly relevant to research and theories on a wide range of behavioral phenomena. His own summary of the theory is as follows (Lindsley, 1951, p. 505):

> The theory rests mainly upon the following points, which are supported by experimental evidence:
>
> 1. The electroencephalogram in emotion presents an "activation pattern," characterized by reduction or abolition of synchronized (alpha) rhythms and the induction of low-amplitude fast activity.

2. The activation pattern in the EEG can be reproduced by electrical stimulation of the brain-stem reticular formation extending forward into the basal diencephalon through which its influence projects to the thalamus and cortex.

3. Destruction of the basal diencephalon, i.e., the rostral end of the brain-stem activating mechanism, abolishes activation of the EEG and permits restoration of synchronized rhythmic discharges in thalamus and cortex.

4. The behavioral picture associated with point 3 is the antithesis of emotional excitement or arousal, namely, apathy, lethargy, somnolence, catalepsy, hypokinesis, etc.

5. The mechanism of the basal diencephalon and lower brain-stem reticular formation, which discharges to motor outflows and causes the objective features of emotional expression, is either identical with or overlaps the EEG activating mechanism, described under point 2, which arouses the cortex.

Lindsley (1952, 1957, 1960) suggested that changes in EEGs and in behavioral efficiency could be related to changes in a continuum which ran from sleep to wakefulness to strong excitement. These speculative formulations posit an inverted-U relation between behavioral efficiency and the behavioral continuum of sleep, wakefulness, and strong excitement. For example, behavioral efficiency is reportedly poor ("lack of control, freezing up, disorganized") at the "strong, excited emotion" end of the behavioral continuum; EEGs consist of desynchronized activity of relatively low voltage and fast frequencies (incidence of alpha is minimal). Behavioral efficiency is relatively good for intermediate segments of the behavioral continuum: during alert attentiveness when EEGs consist mainly of low voltage tracings with less activity above alpha frequencies than occurs during extreme excitement; and during relaxed wakefulness when alpha activity tends to be maximal in incidence and voltage. The next lower level of activation is drowsiness, when EEGs are of lower voltage, with a lower incidence of alpha, and occasional waves slower than alpha may be seen; behavioral efficiency is said to be poor, due to lack of sequential timing and coordination. As we progress towards deep sleep, large slow waves predominate in the EEGs and behavioral efficiency is absent. This seems to say, essentially, that behavioral efficiency is poor or absent at or near both ends of the dimension (sleep and extreme excitement) and behavioral efficiency is good over the not-too-well defined middle segment of the sleep-wakefulness-excitement dimension. Some of the same data and ideas on activating mechanisms are discussed with regard to motivation in Lindsley (1957), and with regard to perception in Lindsley (1958).

Hebb (1955, 1966) pointed out that afferent fibers of the primary sensory pathways apparently have collateral branches which terminate in the reticular formation. He assumed that such collaterals (or an equivalent mechanism) function to provide a general background of tonic excitation without cue properties or steering functions: a general excitation which can facilitate various response tendencies, much as general drive is supposed to do. In fact, Hebb (1955) suggested that arousal level in this sense is the physiological equivalent of the behavioral concept of general drive. In spite of this similarity between the concepts of drive and general arousal level, Hebb's position differs from general drive theory in assuming that there exists an optimal arousal level for performance efficiency. At very high levels of arousal, performance is supposedly impaired, and a decrease in arousal level should result in improved performance; at very low arousal levels, performance is also poor, and improvement of performance should be facilitated by increased arousal. This hypothesis of an optimal arousal level should be distinguished from the general drive view that, provided competing response tendencies do not increase disproportionately, performance of the dominant response tendency simply increases as a function of increasing drive level (up to where inanition allegedly prevents further monotonic increases in effective drive, when food or water deprivation is the source of drive).

Malmo (1957, 1958, 1959, 1962) has argued

for the use of a variety of physiological indicants of a general energizer which may be called general drive or arousal level or activation level. These indices include peripheral physiological response measures, such as skeletal muscle potentials, skin conductance, and heart rate, in addition to more direct measures of activity in the central nervous system. Malmo (1958, p. 250) emphasized that behavioral "general activity" did not appear to be a "promising measure of drive," and proposed that physiological indicants can contribute importantly to the unsolved problem of measuring drive level. Lacey (1967) provides a recent critique of the use of peripheral physiological indices of a single general arousal level in situations where either inter-individual or intra-individual comparisons are made, in studies of prolonged tonic reactions as well as brief or phasic changes in arousal level. Malmo and Bélanger (1967) include an assessment of Lacey's (1967) comments. They acknowledge instances of apparent disassociation or even negative correlations among indices of brief or phasic arousal reactions. They claim, nevertheless, that there is substantial empirical support for the use of physiological indices of general arousal level (that is, tonic rather than phasic arousal).

Theoretical construct of arousal level Arousal level, as a general energizer, is a theoretical construct and its alleged level at any time is inferred from objective data rather than observed directly. Arousal level in this sense might be viewed as the theoretical net result in the central nervous system of all activity in excitatory and inhibitory neural circuits or systems. Viewed this way, arousal level becomes a statistical conceptual device, and the various physiological measures, such as EEGs, muscle potentials, heart rate, blood pressure, and skin conductance, are seen not as actual measures of arousal level, but only as indicants of the arousal level (see, for example, Stevens, 1951, on the distinction between measures and indicants).

Since physiological indicants of arousal level involve response mechanisms, a distinction between phasic and tonic responses is relevant. A phasic response refers to the situation where a stimulus evokes a physiological response with a more or less characteristically short latency and the response is of relatively short duration (a fraction of a second, up to perhaps a few seconds). On the other hand, a tonic physiological response is one that may persist for several minutes or longer (see, for example, Sharpless & Jasper, 1956). Physiological indicants of arousal level are importantly influenced by tonic arousal reactions and, accordingly, stimulation and associative variables are important considerations in the evaluation of physiological indicants of arousal level.

The physiological indicants of arousal level have the same conceptual status as other response indices of states of the organism. The response status of a physiological indicant of arousal level is especially clear when the indicant is skeletal muscle tension, as represented by electrical recordings of muscle potentials from a group of muscle fibers, or from one or more muscles with electrodes placed on the skin. For example, muscle potentials have been observed to increase progressively during mirror tracing. Such rising gradients occurred reliably not only in muscles of the active arm, but in muscles of the passive arm and elsewhere as well. This might be taken to be suggestive of general activation, but it was noted that muscle loci and individual differences of subjects both contributed significantly to the variance in slope of muscle potential gradients (Bartoshuk, 1955). In addition, although the slopes of gradients in active arm flexors and extensors were significantly intercorrelated, the slopes of active arm gradients were not reliably correlated with the slopes of gradients in the passive arm. This necessarily means that these measures of muscle potentials were importantly influenced by other variables (possibly associative ones) in addition to the possible contribution of a general energizer. Moreover, rising muscle potential gradients have occurred in the absence of any gradients in simultaneously recorded and integrated EEGs (Bartoshuk, 1956; Malmo, 1965). This apparently means that a localized increase in muscle potentials does not necessarily indicate a rise in general arousal level, to the extent that EEGs are acceptable as indicants of general arousal level.

The response status of physiological indicants of arousal level must also be considered when the physiological measures used are autonomic measures (such as skin conductance, blood pressure, or heart rate) and EEG measures. We are not referring here to brief, phasic responses but sustained tonic ones. For example, in an experiment on auditory thresholds, there were both intrasession and interday progressive decreases in skin conductance levels (Duffy & Lacey, 1946). These data are consistent with the view that skin conductance was elevated initially by a tonic response to the general test situation, and that skin conductance decreased as the female undergraduate subjects "adapted" to the general test situation. Systolic blood pressures were significantly higher for psychoneurotics in an experimental situation before the experiment had started than in a familiar ward setting, presumably because of a tonic reaction to the general test situation. Control subjects revealed a progressive decline in systolic blood pressures throughout the experimental session (Malmo, Shagass, & Heslam, 1951). Heart rates have remained significantly elevated in human newborns one minute after a brief, relatively intense auditory stimulus (Bartoshuk, 1962b). Electrical recordings of cortical activity in sleeping cats revealed prolonged, sustained activation patterns after a novel auditory stimulus of intermediate intensity was presented (Sharpless & Jasper, 1956). Similarly, sustained EEG reactions to brief auditory stimulation can be observed in humans (Bartoshuk, 1959), and in some instances the auditory stimulus can change an EEG characteristic of drowsiness (low voltage with occasional waves slower than alpha) into an EEG characteristic of relaxed wakefulness (continuous alpha activity of relatively high amplitude). This series of examples illustrates some of the evidence which reveals the response status of physiological measures used as indicants of arousal level.

To recapitulate, we have referred to some of the evidence and theorizing concerning neural mechanisms that might serve as a general energizer and to their potentially important implications for drive theory. We have also given reasons for our view that any single physiological measure is at best an imperfect indicant of a hypothetical arousal level; such a measure may nevertheless be useful to the extent that it qualifies as a motivational variable.
Figure 18.14. Mean heart rate per minute as a function of hours of water deprivation. Heart rates were recorded while rats were bar pressing for water on a continuous reinforcement schedule. (Bélanger & Feldman, 1962.)

Effects of Traditional Motivational Variables on Arousal

To start with, we will review a number of experiments which have varied food or water deprivation or shock intensity parametrically over a wide range and which report the effect that these traditional examples of an empirical motivational variable had on an assumed indicant of arousal level (which allegedly is equivalent to general drive). Then we will look at some effects of thirst on reflex spinal excitability and of deprivation on EEGs.

Thirst, hunger, and electrical shock effects on heart rate Bélanger and Feldman (1962) found a significant linear relation between heart rate and hours of water deprivation up to the 72 hr tested (Figure 18.14). The rat's heart rate was recorded while it bar pressed for water on a continuous reinforcement (crf) schedule, on which each bar press was rein-

forced with a drop of water. Since the number of bar presses was a curvilinear function of deprivation time (Figure 18.11), with the peak number of bar presses at 48-hr deprivation, the increase in heart rate beyond 48-hr deprivation occurred in spite of the decreasing number of bar presses. Dufresne (1961) found that the rat's heart rate during bar pressing for food on a crf schedule increased monotonically with food deprivation times up to the maximum tested of 48 hr in her first experiment. Heart rates went up somewhat irregularly between the 24 and 60 hr of food deprivation studied in her second experiment, and the curves were virtually identical for the meprobamate-treated and placebo groups, respectively (her figure is reproduced in Malmo and Bélanger, 1967). Ducharme and Bélanger (1961) recorded the heart rate of rats in a Skinner box during bar pressing for water on a crf schedule at 23-hr water deprivation, and they found that heart rate increased as an approximately linear function of milliamperes of shock intensity given to the rat immediately before its placement into the Skinner box (Figure 18.15). In all these studies the relation between heart rate and number of bar presses is a curvilinear one, and so the heart rate changes cannot be attributed simply to the physical work required to press a bar. In fact, Ducharme (1966a) found that, with the lever either in or out, heart rate increased linearly as a function of increasing water-deprivation times between 24 and 72 hr for rats trained to bar press for water in the Skinner box. The slopes of the two curves were similar, but heart rates were ac-

Figure 18.16. Mean heart rate as a function of hours of water deprivation and water-linked conditioned stimuli as incentive-motivational stimuli. Heart rates increased as a function of deprivation times for experimental subjects (solid line) while bar pressing for water (●) in a Skinner box and in the home cage (○). Controls (dashed line) had not been trained to bar press for water and their heart rates in the home cage were not related to the deprivation times shown here. (Modified from Ducharme, 1966b.)

Figure 18.15. Mean heart rate per minute as a function of prior shock intensity in milliamperes. Heart rates were recorded while 23-hr water-deprived rats were bar pressing for water on a continuous reinforcement schedule, after a single shock. (Modified from Ducharme & Bélanger, 1961.)

tually higher when the retractable lever was out than when it was accessible. (Of course, in all these experiments, we are left with the possibility that the animals are active even though not pressing the bar, and that such activity is responsible for at least a part of the heart rate changes.)

Evidence for the importance of incentive-motivational stimuli appears to be provided by Ducharme's (1966b) data. Heart rates were higher in the Skinner box and lower in the home cage, and in both locations heart rates increased as a function of hours of water deprivation when the same rats, trained to bar press for water, were tested under both conditions (Figure 18.16). This shows that bar pressing or ingestion of water are not essential for the increments in heart rate as a function of water-deprivation times. A separate control group, which had not been trained to bar press for water, did not have any significant changes in heart rate associated with water-deprivation times up to 72 hr. In the latter case, presumably the electrodes for recording heart rate had not been associated with water as a reinforcer, and apparently in the absence of reinforcer-linked conditioned stimuli (in this case, water-linked CSs), continued water deprivation up to 72 hr was not in itself sufficient to result in reliable progressive increments in heart rate. In other words, the observations of approximately monotonically rising functions relating heart rates to hours of water deprivation apparently have been dependent on the presence of incentive-motivational stimuli in the form of water-linked CSs.

Research in other laboratories provides at least partial support for the pattern of results noted in the preceding paragraph. Hahn, Stern, and McDonald (1962), and Hahn, Stern, and Fehr (1964) found heart rate to be a linear, and performance a curvilinear, function of increasing hours of water deprivation. With extended practice on a partial reinforcement schedule, rates of bar pressing were stable within sessions and heart rates reflected deprivation levels only after the sessions had been in progress for at least 25 min (Doerr & Hokanson, 1968). Such stability is probably what we should expect after training of this type.

Moller (1963) reported that heart rate was a significantly decreasing monotonic function of continuous food-deprivation time, when recordings were made in a constant environment while rats were behaviorally inactive (that is, apparently in the absence of food-linked CSs as incentive-motivational stimuli). Similar results from recordings in home cages were found by Doerr and Hokanson (1968).

Eisman (1966) found that 48 hrs of water deprivation ". . . under relatively constant environmental stimulation, in the absence of prior conditioning, has no systematic effect on HR in Ss never previously deprived." He also replicated the finding that heart rates were not related to different deprivation times per se, and he found significant positive increments in heart rates during drinking. Eisman (1966, p. 75) concluded with some additional highly relevant observations in his discussion:

> It has been found that when a signal (CS) precedes drinking (US), it quickly acquires the capacity to elicit a tachycardic response (CR) which is always greater than the simple response elicited directly by US. Furthermore, the magnitude of the CR is positively related to the deprivation conditions under which it is elicited, yielding a function compatible with the linear function under discussion.

Dehydration effects on spinal reflex excitability Observations that intracarotid injections of hypertonic saline increase spinal reflex excitability in rats (Wayner, 1964) are consistent with viewing this method of producing dehydration (and "thirst") as an empirical motivational variable (that is, as a method whereby drive can be increased). Intracarotid injections of hypertonic saline resulted in markedly increased amplitude of the monosynaptic reflex discharge recorded from the fifth lumbar ventral root of the rat's spinal cord. The increased spinal excitability has been observed for as long as 25 min, and was reportedly reversed by the injection of distilled water (Wayner, 1964).

There do not appear to be any observations

on whether spinal reflex excitability would be enhanced or depressed by a food-linked CS in food-deprived animals (recall the quotation from Sherrington, p. 796), or by water-linked CS in water-deprived animals. However, observations that food-linked conditioned stimuli reduce the magnitude of startle responses to probe stimuli (p. 808) suggest that such CSs would have tranquilizing effects, with consequent decrements in spinal excitability. Such observations might provide a useful means of analyzing reinforcer-linked stimuli.

Deprivation and satiation effects on EEGs Electroencephalograms during food and/or water deprivations are apparently characterized by what has been called an "activation pattern" of low voltage, fast activity, as compared to the higher amplitude, slow waves of at least one phase of sleep. Any such effects of food and/or water deprivation on EEGs, however, should be considered in relation to the behavioral evidence that during food or water deprivation there is an increased responsiveness to external stimuli in general, and especially to food- or water-linked CSs, and that thwarting (frustrative nonreinforcement) may produce arousal reactions. We will consider how food- or water-linked CSs influence the background EEG activity of appropriately deprived animals, and whether food- or water-linked CSs may be considered as activators and/or deactivators.

To explore EEG activity in thirsty rats (dehydrated by either 23.5 hr of water deprivation or by stomach loads of hypertonic saline), cortical and subcortical activity were sampled in each rat (Steiner, 1962). Although electrode placements in the anterior and posterior cortex, septum, and hypothalamus, in general accord with an activation view, revealed relatively less slow wave activity during the water deprivation than the water-sated condition, interpretation of these EEG data is made difficult by interactions among electrode loci, EEG frequencies, and the thirst-satiation conditions. Furthermore, it is difficult to determine the extent to which interactions among the thirst conditions, external stimulation in general, water-linked conditioned stimuli as incentive-motivational stimuli, and frustrative nonreinforcement influenced the EEG records.

Sadowski and Longo (1962) observed activation EEG patterns in the food-deprived rabbit as soon as it was placed in a soundproof room where it had been reinforced whenever an instrumental response occurred in the presence of a buzzer. In trained rabbits, presentation of the buzzer to hungry subjects had the effect primarily of altering the hippocampal tracing, wherein the 4–6 waves per second were replaced by slightly faster waves (up to 8–9 per second) of slightly higher voltage. When the subjects became "satiated" in the experimental cage, they did not perform the instrumental response even when the buzzer was sounded, and their EEGs were now characterized by high voltage slow waves of about 2–3 per sec, with intermittent spindle activity in the anterior cortex. During this "satiation" phase the buzzer had no effect on the EEGs. Nevertheless, when a rabbit was returned to its home cage, it typically consumed its daily food ration immediately. Sadowski and Longo (1962) suggested that the cessation of instrumental performance in the experimental situation after 20–30 reinforced responses was due to inhibition produced by the conditioning procedure, and that another environment (the home cage) resulted in disinhibition.

Activation EEG tracings have been observed in food-deprived rats and more slow wave activity was present in the food-sated than in the food-deprived condition (Hockman, 1964). The results were essentially similar for recording electrodes in the mesencephalic reticular formation, and the ventromedial and lateral hypothalamic nuclei, respectively (in the so-called "satiety" and "feeding" areas or systems, respectively, in the hypothalamus). An explicit analysis was not made in this study of the effects of food deprivation per se on the EEGs, nor of the contributions of external stimuli, including food-linked CSs as incentive-motivational stimuli.

In general correspondence with the observations of increased amounts of slow wave activity in the EEGs of food- and water-sated rats, we may note behavioral and EEG evidence of

drowsiness and "sleep" in female rabbits following coitus (Sawyer & Kawakami, 1959). The "sleep" phase was followed by a "hippocampal hyperactivity" phase which is characterized by high amplitude 8/sec EEG waves in the hippocampus and its projections, and a further decrease in skeletal muscle tonus and slowing of heart rate and respiration. The postcoital latency of the hippocampal hyperactivity was about 13 min on the average, but it varied between about 4 and 23 min for 11 rabbits, and it apparently failed to occur in 2 rabbits. This hippocampal hyperactivity phase reportedly lasted only a few minutes; it was followed by behavioral arousal and behavioral activity, as well as a transition from the hippocampal hyperactivity to lower voltage, less rhythmic electrical activity.

Clemente, Sterman, and Wyrwicka (1964) investigated explicitly the occurrence of a discrete EEG shift in activity immediately after an instrumental response had been reinforced with food, and they called this phenomenon "postreinforcement EEG synchronization." Cats were food deprived for 23.5 hr and tested daily for about 20 min. They were trained to press a cup for food. Each cup press was reinforced with 0.25 ml of a liquid food. After several days of training, the typically low voltage, fast activity of the EEG was sometimes briefly interrupted by a burst of high voltage (100–150 microvolts) slow waves (4–8 per sec), which occurred after the cat pressed the cup and during the consumption of the liquid food reinforcer.

This postreinforcement cortical synchronization was absent after a novel external stimulus (hand clapping) and after electrical stimulation of the ascending reticular activating system, even though there was no observable behavioral disruption in several cycles of instrumental and consummatory activities. A classical conditioning experiment provided evidence that the postreinforcement EEG synchronization can be made to occur in the form of a conditioned response.

Subsequently, more extensive behavioral and quantitative analyses have revealed that the "postreinforcement EEG synchronization" is not uniquely associated with reinforcement of instrumental activity as it is typically defined, and that there are statistically reliable bases for differentiating between EEG patterns of synchronization associated with "relaxation" and "inhibition" behaviors, respectively (Roth, Sterman, & Clemente, 1967).

In conclusion, it appears to be necessary to view at least some aspects of EEG activity as responses (or the concomitants of responses) that can be influenced by reinforcers, incentive-motivational stimuli, and by discriminative stimuli that are correlated with the subsequent reinforcement of specified behaviors. In other words, the effects of food or water deprivations on EEGs appear to vary with the specific experimental conditions at the time EEGs are recorded. Likewise the effects of stimuli on the EEGs of hungry or thirsty subjects are likely to depend on how specific stimuli are related to instrumental activities and reinforcers.

Conclusions on heart rate, spinal reflex excitability, and EEG data A major conclusion derived from this research is that results obtained with various physiological measures during hunger or thirst depend on environmental stimuli and the way in which these stimuli are related to the actual occurrence of instrumental and consummatory activities. For example, a localized EEG burst of high voltage, slow waves was observed in hungry cats drinking milk, and such a localized burst of large slow waves was also elicited by a food-linked CS (Clemente et al., 1964). Similarly, it looks as if cardiac acceleration occurs in rats during the consumption of water or food, and that appropriate water- or food-linked CSs can elicit cardiac acceleration as a conditioned response (for example, Eisman, 1966). When availability of food was made contingent on the prior occurrence of a particular localized burst of EEG activity (Sterman & Wyrwicka, 1967), the incidence of this EEG activity increased significantly (that is, a localized burst of large slow waves, for example, was reinforced with food). Recent data also show convincingly that changes in heart rate can be differentially reinforced as an instrumental

response (DiCara & Miller, 1968; Katkin & Murray, 1968; Miller & Banuazizi, 1968). Thus EEG and cardiac data obtained during hunger and thirst states might be influenced by food or water as elicitors of "unconditioned" responses, by food or water as reinforcers, and by food- or water-linked CSs.

Considering these observations, we may tentatively make these conclusions. Heart-rate data are in agreement with stabilimeter data: food or water deprivations are not sufficient to raise heart rates or stabilimeter activity levels of adult rats. Data on heart rate, spinal reflex excitability, and stabilimeter activity levels are in agreement in revealing greater responsiveness to stimulation in thirsty rats (and this may be true for hungry rats as well). It seems likely that the activation patterns noted in EEG studies of hungry or thirsty rats also reflect a similar enhanced activating effect of stimuli in food- or water-deprived versus satiated states. Finally, the effects of food- or water-linked CSs appear to vary in ways that at present are inadequately understood. Data on heart-rate and stabilimeter activity of adult rats are consistent with water- and food-linked CSs having excitatory effects (higher heart rates and increased behavioral activity). There do not appear to be any recent relevant experimental data on reinforcer-linked CS effects on spinal reflex excitability of appropriately hungry or thirsty subjects. The EEG data seem to indicate that in the presence of food- or water-linked CSs, appropriately deprived subjects are likely to have activation patterns, except perhaps for certain localized EEG effects.

The greatest discrepancy with this current over-all pattern of results is found in studies of startle responses. Whereas food deprivation enhances the magnitude of startle evoked by a probe stimulus (which is consistent with greater spinal reflex excitability in thirsty subjects, and the cardiac and stabilimeter data), food-linked CSs reduce the magnitude of startle, and this appears to be inconsistent with data on stabilimeter activity, heart rate, and some of the EEG data. It is possible that these data on reduced startle during the presence of a food-linked CS may be due to postural or locomotor effects. In our earlier discussion of fear as an acquired source of drive we noted that a CS linked with shock to a rat's feet was likely to become a CS for crouching, which enhanced startle. Perhaps a food-linked CS reduces crouching by eliciting a raised posture or exploratory perambulation. In comparing these various measures in separate studies we should recall that rats, cats, and rabbits have been subjects, and differences attributable to species may be important. At the same time it appears that at least some distinction is required between a stimulus linked with food which serves as a discriminative stimulus for instrumental activity and a CS which consistently precedes the occurrence of food independently of any behavior. This means that to understand the effects of hunger and thirst on spinal reflexes, autonomic reactions and EEG activity, it will be necessary to undertake detailed analyses of environmental stimuli and their functional relations to instrumental and consummatory activities.

Stimulation Effects on Arousal Level

Our introductory discussion of activation or arousal theories revealed the important role assigned to the arousal function of all stimuli. One can inquire, therefore, whether physiological response measures, as indicants of arousal reactions, vary systematically with stimulus intensities which can be varied over an appreciable range, and for which there are meaningful scales. Secondly, environmental stimuli are likely to elicit exploratory behavior, and one can examine whether the exploration of stimuli is related to arousal level and to the arousal effects of these stimuli. Thirdly, direct electrical stimulation of arousal brain sites can be used to vary arousal level, and the behavioral consequences of arousal mechanisms may be studied in this way.

Intensity of external stimuli Hovland and Riesen (1940), with undergraduate subjects,

found that skin potential responses to a 1000-Hz tone increased in magnitude as a positive monotonic function of the decibel level above the psychophysical threshold. When response magnitude and stimulus intensity are both expressed in logarithmic units, the resulting curve has a slight but definite downward curvature. In human newborns, the logarithm of cardiac acceleration increased as a positive monotonic function of the sound level of a 1000-Hz tone (Bartoshuk, 1964). The exponent for the neonatal data was about 0.53, which is surprisingly close to psychophysical estimates of exponents for loudness. These data on galvanic skin responses and cardiac acceleration elicited by auditory stimuli appear to illustrate the diffuse or general activation attributed to all stimuli by activation or arousal theories. Not only does this "activation effect" depend in part on stimulus intensity but, more importantly, these data are suggestive that the "activation effect" of stimulus intensity might vary in accordance with a power function for at least an appreciable range of intensities. Perhaps with appropriately refined techniques one might find that "arousal reactions" and psychophysical magnitude estimations are similar functions of stimulus intensity.

Exploration of external stimuli Harlow (1953a, b) emphasized that food- and water-sated primates spend a great deal of time in manipulatory and exploratory activities, and that these activities are intrinsically reinforcing. Curiosity about external stimuli increases progressively from monkeys to anthropoid apes and man. Hebb (1955) has likewise emphasized the attractions of problem-solving situations for primates. He suggests (1955, 1966) that when the arousal level is below the optimal level, there is a positive attraction to situations involving risk-taking and mild fear, which are likely to raise the arousal level closer to an optimal level.

Butler (1957) maintained rhesus monkeys individually in a test box for periods of 0, 2, 4, or 8 hr during which time they were not exposed to any visual stimuli from outside the test box. Next, a Plexiglas sheet was inserted between a small window opening and an outside door. Pushes on the Plexiglas opened the door on a variable-interval reinforcement schedule. The door remained open for 12 sec and this permitted the experimental subject to see the monkey colony outside the test box. In a 1-hr test monkeys averaged over 400 responses for this visual reinforcer. The number of instrumental responses in a 1-hr test increased monotonically and significantly with the number of hours since the monkeys were last exposed to visual stimuli from outside the test box.

The term "exploration" may be misleading in some instances when the reinforcers are quite simple stimulus changes. For example, Premack, Collier, and Roberts (1957) found, with rats, that rate of bar pressing for weak light onset increased with light deprivations of 12, 24, and 48 hr respectively. When monkeys were submitted to prolonged light deprivation during infancy they subsequently pressed at very high rates for unpatterned light (Wendt et al., 1963). Control data in this study and in Fox (1962) supported the conclusion that light deprivations during infancy are more effective than similar deprivations in older subjects.

College students have been submitted to "information deprivation" by means of isolation in a lightproof room, with earplugs and earmuffs to attenuate sounds (Jones, Wilkinson, & Braden, 1961). Pressing a button produced a pattern of lights in the otherwise featureless room. In one experiment, subjects were allowed to press the button only after either 1 or 5 hr of deprivation. Subjects with 5 hr deprivation emitted more responses during the initial hour of access to the button (see also Jones, Gardner, & Thornton, 1967).

These experiments appear to be consistent with the view that deprivation of light, varied stimuli, and/or information are sources of drive, and that an instrumental response is reinforced by the drive reduction produced by the presentation of appropriately varied

stimuli. However, it also may be argued that the stimulus configurations which serve as reinforcers elicit an increase in arousal level which has fallen below optimal values in the isolation-type environments. Berlyne and McDonnell (1965) cite supportive data on galvanic skin responses (GSR) and EEGs, and they present additional EEG evidence on the blocking of rhythmic alpha activity (flattening of EEG traces) by various 3-sec projections of visual patterns. The durations of the periods that synchronous, rhythmic EEGs were replaced by desynchronized, flattened EEG tracings were significantly related to the complexity and incongruity of the test stimuli. Desynchronization of the EEGs persisted longer when more complex or incongruous visual patterns were presented than when simpler patterned stimuli were presented. The authors interpret their results as congruent with the view that (p. 156): "A substantial body of experimentation has shown exploratory responses to occur as part of a comprehensive 'orientation reaction,' which includes all the indices of heightened arousal. . ." The hypothesis that arousal levels are progressively lowered during conditions of prolonged, homogeneous, monotonous stimulation receives some support from evidence of progressive slowing of the dominant EEG rhythms over the occipital areas of human adults during 14 days of perceptual deprivation (Zubek, Welch, & Saunders, 1963).

It will not be possible to review in detail the various studies on curiosity and exploration, but because of their important implications for any comprehensive theory of motivation we will briefly note here several additional references. Fowler (1965, 1967) has provided systematic analyses of the antecedent conditions of stimulation as sources of drive and of the test stimuli used as reinforcers, together with an emphasis on reinforcer-linked CSs as incentive-motivational stimuli. Arousal approaches to curiosity and exploration are represented in Berlyne (1960, 1966, 1967), Fiske and Maddi (1961), and Hunt (1963).

To recapitulate, we may tentatively conclude that arousal levels are not necessarily elevated and they may be lowered somewhat during prolonged exposure to homogeneous stimulation and perceptual or information deprivation. The view that information or perceptual deprivation per se does not elevate arousal level is analogous to the view that food or water deprivation per se, in the absence of relevant incentive-motivational stimuli, tends to either lower heart rates slightly or have no effect on heart rates as indicants of arousal level; indeed, in some cases we have even noted EEG and behavioral evidence of sleep in food-deprived animals. Similarly, subjects apparently have gone to sleep in an information-deprivation situation (Jones et al., 1967), perhaps in spite of any residual information deprivation as a source of drive, although this cannot be readily assessed in the absence of instrumental activity.

Electrical stimulation of arousal brain sites To investigate whether behavioral efficiency is a function of arousal level in an awake, behaving subject one can attempt to manipulate the arousal level without introducing associative cues by electrical stimulation of brain sites which allegedly form part of a neural arousal system. Although this approach has yielded some interesting results, there are probably too few studies available to permit unequivocal interpretations.

In a much cited study, Fuster (1958) trained six monkeys to perform a series of difficult discriminations. He found that speed and accuracy of the discriminations were improved during relatively weak stimulation and impaired during stronger stimulation of the brain stem. The deleterious effects of more intense stimulation of the brain stem may be attributable to associative factors (for example, the elicitation of incompatible activities such as eye movements and startle reactions) rather than to heightened arousal (see Fuster & Uyeda, 1962, as well). Similarly, the data of Wilson and Radloff (1967) may in part reflect associative effects of electrically elicited brain activity rather than purely arousal effects.

With regard to the equivalence of arousal
Figure 18.17. The effects of changes in general drive level on the relation between "yes" responses and stimulus intensity in a psychophysical experiment. On the basis of a theoretical analysis referred to in our text, an increase from low drive (solid line) to high drive (dashed line) is expected to increase the steepness of the psychophysical function, but the absolute threshold (stimulus intensity corresponding to 50 percent "yes" responses) should not be altered. (Brown, 1961.)

level and general drive which has been hypothesized by some theorists (Hebb, 1955; Malmo, 1958), it is interesting to note that the data of Fuster (1958) may differ in a very important way from the predictions which logically appear to follow from general drive theory. At absolute threshold levels in a psychophysical experiment, Brown (1961) observed that "yes" and "no" responses are equally likely, and an increase in the drive multiplier should not favor either response. Whenever a difference in the habit strength of the "yes" and "no" responses exists, an increase in the drive multiplier amplifies the absolute difference between the two response tendencies. Therefore, as illustrated in Figure 18.17, if only the drive multiplier is increased and the associative habit strengths are not changed, then the psychophysical curve relating the proportion of "yes" responses to stimulus intensity should become steeper throughout the central intermediate range of those stimulus values which elicit the same response less than 100 percent of the time. Fuster (1958) used exposure times of 10, 20, 30, and 40 msec for the test stimuli, and on control trials the percentage of correct responses was slightly below 50 at the shortest exposure and increased monotonically to a high of about 85 percent at the longest exposure. On experimental trials, the curve for percent correct appears to have been simply displaced upwards; experimental and control curves are approximately equidistant from each other for the four pairs of data points. Even when control performance was slightly below 50 percent correct, the improvement in accuracy produced by electrical stimulation of the brain stem was as great as for the 20-, 30-, and 40-msec test exposures which had yielded about 70 to 85 percent correct on control trials. The lowest mean percentage correct in Figure 4 of Fuster and Uyeda (1962) is about 57 and it occurs on control trials at a 10-msec test exposure. Here again, the experimental and control curves of percentage correct do not appear to depart systematically or significantly from being equidistant from each other for the four pairs of data points. These results appear to be consistent with the suggestion made by Fuster and Uyeda that electrical stimulation of the mesencephalic reticular formation lowered the tachistoscopic recognition threshold rather than just elevating general drive.

Lindsley (1957, 1958, 1961) has reported that electrical stimulation in the reticular formation can improve the resolving ability of the visual system. When a light flash of 10 μsec duration was presented twice, two evoked responses were recorded on the cat's visual cortex provided the interflash interval was long enough. When the interflash interval was only 50 msec, only one cortical evoked response was discernible. For about 10 sec after electrical stimulation in the reticular formation, two cortical evoked responses were discernible even with an interflash interval of 50 msec.

Mahut (1964) has investigated the effects of low intensity, 10-sec stimulation of subcortical loci on discrimination learning in cats with food as a reinforcer. Stimulation during

choice behavior significantly enhanced learning. Improved visual function was considered an unlikely explanation of the facilitatory effects of electrical stimulation because the test objects were large and exposed for 10 sec. To the extent the electrical stimulation during choice behavior increased arousal level, such slight increments in arousal during discrimination learning would have accompanied both correct and incorrect responses. Mahut tentatively attributed an attentional function to any arousal increments responsible for the facilitatory effects of stimulation.

Chemical stimulation of the reticular formation has been explored in behavioral studies of instrumental activities as well. Nakajima (1964) injected electrolytes (sodium, potassium, and calcium chloride) into the mesecephalic reticular formation of rats. He found impairment of lever pressing for food, and both significant increases in activity wheel running (by calcium) and suppression (by potassium). Grossman (1966) has extended his work on the use of selective activation of neural mechanisms by chemical means to a study of the midbrain reticular formation of rats. Avoidance behavior was especially susceptible to impairment by implant treatments which did not interfere with an instrumental escape response.

Although some of the results we have considered are consistent with the view that direct stimulation of "arousal" areas of the brain serves as a general energizer, the results are far from conclusive.

Do Indicants of Arousal Meet the Criteria for Motivational Variables?

In our discussion of objective criteria for the identification of an empirical motivational variable, we concluded that apparently the three most generally accepted criteria are that a motivational variable is a general energizer, its onset punishes, and its offset reinforces.

General energizer Throughout our discussions of energizers we have indicated that it has been extremely difficult to devise meaningful tests to assess whether an empirical variable genuinely functions as a *general* energizer. These difficulties arise from the need to rule out confounding associative effects and possible selectively energizing mechanisms. Incentive-motivational stimuli (such as food- or water-linked CSs) appear to be a major source of selective effects that can be mistakenly attributed to a general energizer.

The most extensive, systematic data discussed here on a physiological indicant of arousal level for different degrees of food and water deprivation are provided by the series of heart-rate studies. The evidence we have reviewed on heart rate as an indicant of arousal level tends to support the following conclusions. Heart rates are not elevated by food or water deprivation per se; heart rates of water-deprived rats are elevated during the drinking of water and even in the absence of water, provided water-linked CSs as incentive-motivational stimuli are present; similarly, heart rates of food-deprived rats are elevated during the consumption of food, and probably in the mere presence of food-linked CSs as incentive-motivational stimuli. Thus the heart-rate data reflect incentive-motivational effects, at least to some extent. We have also noted that EEGs are likely to be influenced by incentive-motivational stimuli, and that both EEG and heart-rate changes can be reinforced.

In our discussion of incentive motivation we noted that a relation between instrumental performance and a reinforcer-linked CS does *not* prove that incentive-motivational stimuli are a source of *general* drive. At least some of the effects of food- or water-linked CSs (as incentive-motivational stimuli) on instrumental performance are undoubtedly associative (Logan, 1960, 1966; Bower, 1961).

In attempts to rule out confounding associative effects, startle has been selected as a criterion response in some behavioral studies because the startle response does not have a past history of reinforcement in the test situation, and there normally would have

been no opportunity for the reinforcer-linked CSs, as incentive-motivational stimuli, to form associations with the startle response. Some such criterion response measure which has not formed associations with the incentive-motivational stimuli in the test situation is required. For a definitive assessment of these heart-rate studies we need to know more about the associative and activating and/or deactivating properties of food- and water-linked CSs as incentive-motivational stimuli, and we need to know whether heart rates can be used to predict the magnitude of a criterion response measure which has not been associated with the food- or water-linked CSs as incentive-motivational stimuli.

Reinforcing and punishing criteria Application of the other two criteria for the identification of an empirical motivational variable requires the demonstration, for example, that cardiac acceleration punishes immediately preceding responses and that cardiac deceleration reinforces immediately preceding responses. There apparently have not been any direct tests of these criteria with hungry or thirsty rats. Since cardiac acceleration has been elicited by water-linked CSs, which are likely to reinforce rather than punish, and cardiac acceleration occurs during drinking water by thirsty rats, it seems highly unlikely that these levels of cardiac acceleration in thirsty rats could be shown to punish responses which lead to water-linked CSs and water. The view that increases in arousal are not necessarily punishing is consistent with evidence of sites in the reticular activating system where arousal can be elicited at low thresholds of electrical stimulation without any apparent reinforcing or punishing effects (Olds & Peretz, 1960).

Tenability of Arousal Level as a General Energizer

In our discussion of experiments on arousal we have questioned whether various experiments have provided definitive evidence for the view that arousal level functions as a general energizer, and we have suggested in several instances that alternative intepretations of the data were possible. Although we have tended to emphasize difficulties in finding definitive positive evidence for arousal as a general energizer, this does not mean that we have intended to argue against the tenability of hypothetical arousal mechanisms which could function as a unitary general energizer. We should add that neither do the negative data and criticisms currently available appear to be definitive.

The hypothesis of an arousal system as a general energizer may seem to be highly implausible for several reasons, based especially on neuroanatomical data, and the effects of drugs and lesions. Thompson (1967) provides a useful summary of the "classical view" of the ascending reticular activating system (ARAS) of the mid-1950s and of recent developments. He notes that even in 1954 some 98 histologically distinguishable reticular nuclei were reported, and he cites various studies which have demonstrated that EEG arousal and behavioral arousal can be dissociated by the use of drugs and by certain lesions. At the beginning of his discussion of recent developments, Thompson (1967, p. 435) noted that, "While these anatomical findings contrast with earlier views of the structural organization of the ARAS, they do not necessarily contradict the classical view of the *functional* organization of the ARAS."

On the general question of the relation between structures and functions, perhaps a few illustrative questions about the visual system may be helpful. Cyclopes might argue that men with two spatially separated eyes must normally have double vision; if they found the appropriate patients with neurological lesions or disorders, or under the influence of appropriate drugs, their hypothesis would seemingly be confirmed. The neuroanatomy of the visual system is complex and, perhaps on this basis, the hypothesis of a perceptually unified visual field would be rejected by some one-eyed theorists as a highly implausible one, while others might be inclined to retain

it as a useful working hypothesis. Similarly, in spite of the neuroanatomical complexities, and the data obtained from dissociations by drugs and lesions, it seems that a general energizing functional system may still be quite possible. It is noteworthy that it apparently can be difficult, for example, to account for the sparing and recovery of function after lesions (especially when they are done in two stages, or in comparisons of the effects of lesions incurred during infancy versus adulthood); such sparing and recovery of function has been observed not only in the reticular system, but in the visual (Meyer, 1958), somatic sensory (Benjamin & Thompson, 1959), and motor (Travis & Woolsey, 1956) systems as well.

The existence of selective associative effects, and the probable existence of selective energizing effects, does not logically rule out a general energizer. Berlyne (1967), for example, has noted the possible analogy with research on intelligence where models with both a general and various specific factors have been explored. To change analogies once more, if one collected data on velocities attained by feathers, stones, and other objects dropped from the roof of a building, there might be a lack of agreement in results for different objects, and such data would be unlikely to provide good support for Newton's gravitation constant. In this case, however, Newton's conception of gravitation is less at fault than our proposed rooftop experiment. Perhaps the arousal (and general drive theory) formulations of a general energizer can be improved to specify better under what conditions the most relevant experiments can be performed.

OVER-ALL CONCLUSION

Throughout this chapter we have been evaluating the hypothesis that behavioral response measures vary as a function of the degree of deprivation. As we have seen, much of the available data is not easily reconcilable with the hypothesis that behavior is the product of habit strength multiplied by general drive, even when drive is corrected for inanition. Instead, the forms of the functional relations are quite clearly influenced by such factors as the nature of the response measures, specific reinforcement schedules, means of manipulating deprivation, and species differences.

Deprivation operations probably selectively favor the occurrence of relevant consummatory responses, and this bias probably increases as deprivation increases. So, in part at least, some of the decrement in instrumental responding at high levels of deprivation may be attributable to interference from consummatory (and closely related) responses.

This view would suggest that each behavioral situation and each deprivation procedure might combine in a unique fashion, for different consummatory responses would interfere with different instrumental responses to varying degrees at each deprivation level. Were this the case, there would be no general solution to the problem of how behavior is influenced by drive level (as inferred from empirical motivational variables). In essence, this appears to be true for contemporary motivational research, although some may still believe that a more general solution is eventually attainable.

Charles N. Cofer

PROPERTIES OF VERBAL MATERIALS AND VERBAL LEARNING

19

This chapter is concerned with verbal learning and with certain of the variables that are known to help or hinder it. Our major goal is to describe the ways in which verbal materials differ from one another, for such differences have important relations to the efficiency of verbal learning. In discussing such differences, we shall, to a large extent, be dealing with *association,* a term which designates concepts that have a long history and refers to problems and procedures that have figured in psychology since almost the beginning of its history of experimentation.

The term *verbal learning* denotes a field of inquiry of which the focus of interest lies in the phenomena of and the processes by which individuals come, through practice, to link two verbal items together, to learn the sequence in which a set of verbal items occurs, to differentiate between verbal items, or to recall a set of items without regard for the order in which they occurred originally. There are, then, four major methods or procedures that are used, in the experimental laboratory, to study the phenomena and processes of interest: paired-associate learning, serial learning, verbal discrimination, and free recall. These are the names of the major tasks which are employed, although there are, of course, variants of each.

The systematic experimental study of verbal learning began when Hermann Ebbinghaus (1885) initiated his experiments on serial learning. Ebbinghaus' interest lay chiefly in the retention

or forgetting over time of material we previously have learned; however, in order to study retention he realized that it was necessary to specify, first, what had been learned, and, second, the conditions prevailing at the time of learning. Many of the problems Ebbinghaus studied are taken up in the succeeding chapters. One particular innovation he introduced, however, has direct concern for us here.

Ebbinghaus invented the nonsense syllable in order to provide units that are unrelated to one another and are equal in size and significance. He wished to avoid the problems of word meanings, the interrelations among words, and their differential significance for the sense of a sentence. The nonsense syllable consists of two consonants with a vowel between them, with the condition that the result be a meaningless unit. Thus, one might write "DAJ," "GEX," "MUB," and so on (in English). Syllables of this kind are often referred to as CVCs (consonant-vowel-consonant) to distinguish them from another kind of trigram, the CCC, which consists entirely of consonants.

A number of writers (Irion, 1959, p. 541; Deese, 1961, p. 14; 1965) have observed that Ebbinghaus' studies represent the development and application of experimental methods for the study of *associations*. They suggest that Ebbinghaus' work was an outgrowth of the tradition in philosophy, especially British philosophy, known as "Associationism." This tradition, some of the notions of which we summarize below, exerted a major influence on the development of psychology, although it was, in the hands of the philosophers, not connected with laboratory experimentation.

Ebbinghaus (1885, p. 33) initiated his formal experiments in 1879–1880. In that same period, Francis Galton (1879–1880) reported studies of association of a rather different kind. Among other procedures, Galton determined what thoughts occurred to him when he looked at words one at a time. His procedure was the forerunner of word-association tests, which, like Ebbinghaus' methods, continue to be employed. Word-association tests, however, were not often used in conjunction with Ebbinghaus' procedures until about 1950. Thus, since their inception verbal learning and word association have been separate fields of inquiry. Since about 1950, however, these fields have come into major interaction. (Consequently, the chapter on Association, which stood alone in the editions of this book published in 1938 and 1954, has for the present edition been retitled, and its content has been drastically modified.)

We may suppose that word-association tests give evidence of characteristics of words and of their interrelationships that have been built up by a subject from his experiences with his native language. Ebbinghaus' nonsense syllables are not words, but there is now abundant evidence that they are not all nonsensical. Nonsense syllables are constructed from the letters of a language, and the fact that they are not, in many instances, without sense and the fact that they differ from one another in various ways may be attributed to the subject's experience with the letters and with their combinations in his language. In other words, Ebbinghaus was not successful in constructing equal and meaningless units, a fact he recognized when he said of series of syllables that they "exhibit very important and almost incomprehensible variations as to the ease or difficulty with which they are learned" (p. 23). A major field of work has grown up with respect to the ways in which the differences among "nonsense" materials may be described and assessed. There are similarities between the procedures for doing so and those involved in word-association tests, though there are differences, also.

In this chapter we are concerned first with describing the characteristics of verbal materials, sensical and nonsensical, when the concern is with the individual item. However, interest has also been shown in the effects of the grammatical organization of items, as exemplified in poetry and in prose. We are, therefore, also concerned with connected materials, and we shall wish to ascertain the

effects of item characteristics and of grammatical organization in verbal learning situations. The major burden of this chapter is to describe these matters, but attention also is devoted, at suitable places in the account, to questions of theory, both with respect to item characteristics (such as association) and grammatical organization and with respect to the nature of the learning tasks in which the effects of the characteristics and the organization are investigated. But first we take a further brief look at history.

HISTORICAL BACKGROUND

Although Plato made some comments (in the *Phaedo*) that seem to refer to association and some of its possible laws, it was Aristotle who, according to Warren (1921), achieved the fullest account of association in antiquity. Aristotle pointed out in the *De Memoria* that in the sequence of ideas in a train of thought the ideas that appear one after another bear relationships to each other, that is, they are similar, they are in contrast, or they have been present together at the same time in the thinker's past experience. Similarity, contrast, and contiguity in space or time were later referred to as *laws of association* or as the *primary laws of association.* A long period of time elapsed between Aristotle's enunciation of these processes of association and their active and affirmative use as major factors in the development and the functioning of the mind. It was Thomas Hobbes (1588–1679) who made the processes of association important features of his philosophy and psychology, and emphasis on association was a hallmark of British philosophy for two centuries thereafter.

According to British Associationism or Empiricism, the nature and the contents of the mind are held to be the results of experience. In general, the source of knowledge, according to this view, is sensation produced by the impact of the outside world. These sensations, and their weaker copies, Images or Ideas, are hooked together or amalgamated by the automatic processes of association—hence the importance of the laws of association. On this basis, the Associationists offered detailed and often complex accounts of such processes as thinking.

That there are three primary laws of association is a proposition that was not always accepted. For example, some of the Associationists made contiguity the primary law and attempted to derive similarity and contrast from it. To the contrary, other writers, such as Thomas Brown (1778–1820), accepted the three primary laws but added other laws, called *secondary laws.* In his secondary laws, Brown postulated factors in the formation of associations some of which later empirical investigators were to study extensively. The secondary laws are (1) *duration,* (2) *liveliness* (or vividness), and (3) *frequency,* all of which refer to the characteristics of the original experiences brought into association by contiguity and which, therefore, state conditions of learning; (4) *recency,* and (5) *freedom from competing associations,* which seem perhaps to refer to factors involved in the retention or forgetting of associations; (6) *constitutional differences among individuals,* (7) *emotional variations in the same individual* at different points in time, (8) *temporary states,* for example, health, and (9) *prior habits of life and thought,* which represent a recognition of the variability in behavior that occurs between individuals and within an individual in time and suggest factors that may be involved in this variability.

It should be clearly understood that the importance of association and the nature of its laws were problems dealt with by the British Associationists by means of analyses of their own experience. They analyzed their thinking processes and attempted to recall or discover the possible factors, past or present, responsible for the occurrence of ideas together in thought. These men did not conduct experiments, but when experimentation was undertaken, as it was by Ebbinghaus, it was influenced by or was even designed to test the ideas of these philosophers (Irion, 1959).

Deese (1965) has argued that the processes, laws, and other contributions of the Associationists have *misguided* experimentation because the problems they have set for experimentalists grew out of the introspective account of thought, and the nature of thought as revealed by introspection may have little or nothing to do with the ways in which associations are originally acquired. We discuss this later in describing Deese's contributions concerning the analysis of associations. Mandler and Mandler (1964) have brought together selections from the writings of major associationists as well as from their critics and have offered commentaries on many aspects of the history of the study of association and its conceptualization.

This brief historical sketch should indicate why Galton's study of word association and why Ebbinghaus' attempts to study *de novo* the formation and retention of associations were so important; they represent techniques for actually studying associations, as opposed to introspecting about them. Galton and Ebbinghaus attacked the problem of association in very different ways, but their goals were not perhaps dissimilar. Galton's methods tell us what words are related to one another but nothing about how these relations were established originally. Ebbinghaus' procedures tell us how associations can be formed, and it is at least possible that Ebbinghaus' methods show the kind of things that went on when the associations were formed that Galton measured (see Russell, 1961; Deese, 1965).

PROPERTIES OF VERBAL MATERIALS: DISCRETE ITEMS

Although words and nonsense syllables differ from each other in many ways, several of the procedures for describing and measuring their properties have common features. We may classify these procedures into three kinds: *output methods,* which yield production measures and relational measures, *counts,* and *ratings.* Output methods include the procedures usually referred to in discussions of word association. Many properties of verbal stimuli have been studied by rating methods. In fact, ratings are often used as alternatives to output methods and counts. We shall therefore consider ratings with output methods and counts in the cases where ratings are being used as alternatives to them, reserving, however, to a separate section, the discussion of ratings of properties that are not obtained by means of output methods and counts.

Output Methods

As is suggested above, output methods include the Word Association Test. However, they include other techniques as well, although all of the techniques share a common feature: The subject is asked to respond, one or more times, to each of a set of stimuli, the stimuli usually but not necessarily being verbal. In general, the subjects' responses are used in one of two ways. For one they are used to determine the sheer number of responses the stimulus elicits or that is produced in response to it. This we shall call the *production measure*. The second way they are used is to determine associative relationships between two stimuli or among the members of some set of stimuli. This we call the *relational measure*. The two methods differ, essentially, in what is done with the subject's responses. Because of this fact, we turn first to the description of the actual procedures for obtaining the responses and second to what is done with them and what the measurements have to do with verbal learning.

Procedures in output methods: Obtaining the data Six methods may be distinguished and are named here in accordance with past practice (Woodworth, 1938; Noble, 1952, p. 424, n. 4; Woodworth & Schlosberg, 1954). They involve single or multiple responses, and free or controlled association.

Single-response Free Association. This method involves presenting a stimulus word

(or other item) to the subject, and asking him to respond by giving the first word that comes to his mind, other than the stimulus word itself. The stimuli may be presented one by one in an exposure device, they may be spoken by the experimenter, or they may be read silently by the subject from a list. The experimenter may record the response by means of writing it down or by means of a tape recorder. He also may record the latency of the association by measuring the time that lapses between the exposure of the word and the occurrence of the response. Such times may be recorded by the use of a stopwatch, but a preferred procedure is to use voice key mechanisms which actuate a clock when the stimulus word is spoken and which stop the clock at the first sound made by the subject.

The bulk of available normative data, however, has been obtained by having people write their associations alongside each stimulus word. This procedure enables large amounts of data to be collected quickly, for it can be used with groups of subjects. Obviously, details of the responses, such as their latencies, cannot easily be obtained.

Associations obtained in the ways described above are considered to be free, in the sense that any response is satisfactory so long as it is not a repetition of the stimulus. In other words, no restrictions are placed on the responses that may be given.

Single-response Controlled Association. In all ways but one, what we have said about single-response free association applies to the procedure producing single-response controlled association. The difference is that to produce controlled association the subject is required to give responses of some given type. For example, a subject may be asked to give opposites or synonyms in response to the stimulus words. Here, then, restrictions are placed on what responses can be given in carrying out the task. In the procedure producing free association, any response will do, other than the stimulus word; in controlled association a response must match the requirements set by the instructions for each stimulus.

Multiple-response Free Association. Two methods are involved in the procedure to produce a multiple-response free association. One may be called *continuous association,* the other *continued association.* In the former, the subject responds to the stimulus by giving as many responses as he can within a stipulated interval of time. In doing so, the subject may be responding to the original stimulus or he may be responding or may be encouraged to respond to the responses he has already given. To produce continued associations, however, the original stimulus is repeated a number of times, so that each of the subject's responses is more likely to have occurred to the original stimulus than to responses he has already made. In Noble's method (1952), for example, a given stimulus word is printed on each line of the response sheet, and the subject is instructed to write each of his responses beside the printed stimulus word. This method presumably reinstates the original stimulus to an extent not true of the technique of continuous association.[1]

Multiple-response Controlled Association. The procedure to produce multiple-response controlled associations also involves a continuous or a continued procedure, with instructions setting limits on the kinds of responses that are acceptable.

Is Free Association "Free"? The answer to this question is that we do not know, but that

[1]Woodworth (1938, p. 341) seems to have coined the term *continued association,* although his description does not clearly differentiate it from *continuous association,* a term discussed by Woodworth and Schlosberg (1954, p. 47). Noble (1952, p. 424, fn. 4) adopted the term *continued association* from Woodworth and defined continued associations as "those which are successively elicited by the same stimulus. . . ." Woodworth and Schlosberg (1954, pp. 46–47) have spoken of discrete free association and discrete controlled association as contrasted with continuous association. The present writer has chosen to substitute "single-response" for discrete and "multiple response" for continuous (or continued) association, as giving a clearer indication than the other words of what is required in each task. Noble's method has, in general, been used more commonly than continuous association, and the two procedures for multiple response association apparently have not been compared.

it is probable that free associations are free only in the sense that the experimenter imposed no restrictions on acceptable responses. What restrictions the subject may place on himself we cannot say (see Koffka, 1912) in the general case.

Measuring meaning: the production measures The first use of a procedure and a measure of this type was apparently Glaze's (1928) calibration of the association value of nonsense syllables. Glaze used 2,019 CVCs and determined their association values (*av*) from 15 subjects. Glaze exposed each syllable in a tachistoscope for from 2 to 3 sec, spelling the syllable at the same time. The subject was to indicate what the syllable meant and to indicate that it meant something even if he could not verbalize the meaning. The *av* for each syllable was simply the proportion of the 15 subjects who indicated that a syllable meant something that could be verbalized or not. None of them could find any meanings for JYC (Y was considered a vowel by Glaze), GAX or KYV, whereas all of them found meanings for FAC, LIM, and WIS. The first three syllables thus have 0 percent *av*, whereas the last three have a 100 percent *av*. Of course, many other syllables were found to have values intermediate between these. Hull (1933) and Krueger (1934) used procedures somewhat like the one employed by Glaze in further efforts to measure the *av* of CVCs. Because Krueger used more subjects than Glaze and many more syllables (2,183) than Hull, his values are probably the best. Witmer (1935) measured the *av* for 4,524 CCCs (all-consonant trigrams). [Her data are reproduced by Underwood and Schulz (1960) in their Appendix B. Their Appendix A gives Glaze's and Krueger's values for CVCs.]

We refer to the production measure just described as *association value*. Another technique has been employed by Noble (Noble, 1952; Noble & Parker, 1960). Noble obtained continued associations for 96 dissyllables (2-syllable items, some of which were words and others of which were paralogs, for example, gojey). He then determined the average number of responses given to each stimulus in 60 sec. This gives, according to Noble, the *meaningfulness* or *m* of each item. Noble obtained a value of .99 for *gojey* and of 9.61 for *kitchen*. (His data are reproduced by Underwood and Schulz, 1960, as their Appendix C.) Mandler (1955) scaled the *m* of 100 nonsense syllables by what is essentially Noble's method.

Rating methods for assessing *av* and *m* also have been used. Noble, Stockwell, and Pryer (1957) obtained ratings for 100 nonsense syllables. They asked their subjects to rate each syllable in terms of "the number of things or ideas" it made them think of and to do so on a 5-point scale ranging from None to Very Many. These ratings permitted Noble and his coworkers to compute measures of association value and scaled meaningfulness (*m′*). Scaled meaningfulness was arrived at by converting weighted frequencies for the 5 rating categories into deviates of the normal curve. Noble (1961), using the same methods, has reported association value and *m′* scores for 2,100 CVC combinations obtained from 200 college students. Archer (1960) used 2,480 CVCs and determined the percentage of the 216 students who for a given trigram answered "yes" to any one (or more) of the following questions: "Is it a word? Does it sound like a word? Does it remind me of a word? Can I use it in a sentence?" These percentages range from 1 for XYH to 100 for real words like ZIP (the values are reported in Archer's monograph). Archer's method does not ask for ratings, but it is not exactly a production procedure, either. In general his questions and his procedure of scaling trigrams in terms of the proportion of subjects answering yes to any of his 4 questions are similar to the technique used by Glaze.

The reliability of both the values obtained from production and rating measures is usually reported to be quite high. In collecting his original data on dissyllables, Noble (1952) used 4 separate groups of subjects, each composed of from 27 to 32 airmen. He com-

puted the m values for the items in each of these groups and found intercorrelations between average m values for the groups ranging from .96 to .98; the mean intergroup reliability was estimated at .975. Noble and Parker (1960) used the original 96 dissyllables with 100 college students. They produced, on the average, 2.11 more associations per stimulus than the airmen, but the relative scores for the items were highly stable as indicated by an r of .97. Other investigations (Noble, 1963, p. 85) have also yielded high reliabilities.

Noble (1961, pp. 505, 510) has reported very high reliabilities for his measures of av and rated meaningfulness (m'). Archer (1960, p. 22) reports a test-retest reliability over 48 hours for his measure of .882.

Rather high correlations have been reported, also, for av, m, and m' for sets of items common to different studies. Thus it is of interest to know whether values obtained by Glaze, Hull, Krueger, Mandler, Noble, and Archer are comparable. Summaries of the correlations which have been obtained may be found in Archer, 1960, Table 4; Goss & Nodine, 1965, Table 3, p. 42; Noble, Stockwell, & Pryer, 1957, Table 2; and Underwood & Schulz, 1960, Table 2, p. 16. The majority of these correlations fall between .70 and .90, and in view of variations in procedure, the time at which the studies were done, the unknown comparability of subject samples, and the like, it seems to most writers that these correlations are so high as to indicate that the measures are probably all indicative of much the same basic variable. It should be noted, however, that in some cases correlations are higher when curvilinear relations are taken account of than they are when curvilinearity is ignored. Thus av (Noble, 1961, Figure 4.2, p. 88) increases as m increases up to a point but does not do so as m increases beyond that point. When he plotted Archer's scores for 120 representative CVCs against their m' values, Noble (1961, Figure 7, p. 519) found the relation to be linear only for the middle of the m' scale.

A number of materials and procedures other than those we have summarized here have been reported in the literature. They have been brought together in a convenient tabular form by Goss and Nodine (1965, Table 2, pp. 21–39). We mention some of them again later.

The production measure and verbal learning A major question of interest with respect to all of the procedures and methods we are considering is whether they in fact have relationships to verbal learning. To answer this question requires first that the methods used in verbal learning research be clearly understood. In what follows, each of the 4 major methods is described, together with information pertinent to the question just raised.

Serial Learning. There are several procedures for studying serial learning. However, perhaps the one most often used is called the *serial anticipation method.* Let us suppose that you are to learn a 10-item list consisting of CVCs by this method. The experimenter will use some device, commonly a memory drum,[2] to expose each item one by one. The first thing you would see is some symbol, such as asterisks; this would be followed by the first CVC, then the next one, and so on until the last CVC is exposed (a symbol indicating the end of the list is sometimes presented following the last CVC). These items would be shown in the same order during subsequent presentations or *trials.* On the second trial, however, you would be asked to anticipate what item will come next and to do so before it appears. Thus, when you see the

[2]Methods for exposing materials for learning experiments have been described in Woodworth and Schlosberg (1954, p. 703) and Runquist (1966, pp. 513–514). The basic requirements for any device are that it must expose only so much of the "lesson" at one time as the procedure calls for; and the duration of each exposure must be controllable. In the memory drum, these requirements are met by printing the words or syllables on a strip of paper or cloth and fastening the strip around the cylindrical "drum." A screen hides the drum from the subject; an aperture is cut into the screen to allow one line of the material to be seen; and the drum is moved by discrete steps from line to line, so new material is exposed in the aperture of the screen. In recent years, slide projectors that allow controlled exposure have become relatively inexpensive and are replacing the memory drum in many laboratories.

asterisks you would try to say aloud the first CVC (for example, GAX); when GAX appears, you would know what it was if you failed to say anything at all or whether what you said was right or wrong. Seeing GAX, you would then respond with the next CVC (for example, BUP); seeing it, you would try to anticipate the next one, and so on to the end of the list. Typically, a number of presentations or trials would be necessary before you could anticipate all the syllables correctly. Practice frequently continues until this criterion of learning or of mastery is attained.

Ebbinghaus (1885) studied serial learning, but he did not use the type of method described above. Rather, he read his CVCs one by one (to himself), but after the presentation he attempted to recall the syllables in the order in which they were presented. In other words, he used the method of *serial recall* to study serial learning. Other procedures are sometimes used. For example, after presentation the subject may be given the items, typed on cards, and be asked to reconstruct their serial order.

There is a good deal of consistent evidence indicating that as the association value (*av*) or the meaningfulness (*m*) of the items in serial lists increases, the lists require fewer trials to learn (see Underwood & Schulz, 1960, pp. 27–31, for a review). For example, McGeoch (1930) used CVCs varying in *av*, according to Glaze, and the method of serial recall. When a 2-min study interval was allowed, the mean number of the 10 items recalled was just under 6 for the 0 percent *av* list; for the 100 percent *av* list, the corresponding value was 9. Noble (1952b) found similar effects for serial anticipation learning of CVCs which varied in Glaze *av*. Postman (1961) employed 2-syllable words varying in *m* and also obtained differences in learning with the serial anticipation procedure.

Verbal Discrimination Learning. In verbal discrimination learning (see McClelland [1942]), a series of pairs of verbal items is presented, usually visually, and the subjects are asked to learn which member of the pair is "correct," that is, the one arbitrarily selected by the experimenter as the right one. The subject responds to each pair and is told or otherwise informed whether his choice is the correct one. Again, trials are continued until the subject reaches the criterion of mastery established by the experimenter. Commonly, the members of a pair are presented simultaneously, one above the other, and the position of the correct and incorrect pair members is varied from trial to trial, as is the serial position of the pair in the total set of pairs. However, the pair members sometimes may be presented successively.

Little work has been conducted concerning the relation between *m* or *av* and verbal discrimination learning (see Ekstrand, Wallace, & Underwood, 1966, pp. 575–576). What there is has not indicated important relationships. Keppel (1966) found no significant difference in the number of trials subjects required to learn a list of 12 words and a list of 12 CVCs taken from the range of 34 to 37 percent *av* in Archer's scaling. Postman (1962, Experiment III) studied verbal discrimination learning for 3 lists of pairs, the words in the lists differing in the frequency of their occurrence in the English language from high to low. Presumably, these lists differed in *m* or *av*, for the frequency of occurrence shows a positive relation to *m* and *av* (Underwood & Schulz, 1960, pp. 60–62). However, Postman obtained the most rapid verbal discrimination learning for his lists of words that occurred with medium frequency and the slowest learning with his lists of words that occurred with a high frequency. It is likely that this result, which is not an expected one, is due to associations among words in different pairs; there is evidence that words occurring with a high frequency have associations with other such words (Deese, 1960) to an extent greater than is true for words of lesser frequency of usage.

Free Recall. In the method of free recall a list of items is presented orally or visually to subjects, and each is asked to recall as many of them as he can *in any order in which*

they occur to him. The distinguishing feature of this method is the freedom it gives to the subject as far as the ordering of items in his recall is concerned. Many studies of free recall involve only a single presentation and a single recall, but multiple presentations, each followed by a recall, have been employed. Tulving (1962) has referred to this multitrial method in the case of free recall by the term *free recall learning.* Many investigators using several trials vary the order in which the items are presented in successive trials, although a constant order of items can also be used.

Free recall has been extensively employed since about 1950 because investigators have been concerned with the sequences in which items are recalled and variables related to the occurrence of these sequences. In free recall learning groups of constant sequences of items develop over trials. We shall have more to say later about the variables which relate to free recall learning. The sheer number of items recalled is the measure that has been studied with respect to *m* or *av.*

Postman, Adams, and Phillips (1955) used a list of 20 CVCs, which varied in *av* (Glaze) from 0 to 100 percent. An immediate retention test indicated that free recall varied with the *av* of the CVCs, being poorest for those of 0 percent and 33 percent *av,* being better for those at 66 percent *av* and best for those at 100 percent *av.* However, there were no differences as a function of *av* when a recognition test was used. Postman and Adams (1956) compared the free recall of 30 CVCs (*av* values of 40 and 46.67 percent from Glaze) and of 30 adjectives. Presumably the words are higher in *av* and *m* than the CVCs. Recall was much better for the adjectives than for the CVCs, a result confirmed by Postman and Phillips (1961) with different lists. Although this evidence is not extensive there seems little reason to doubt that *av* and *m* relate positively to the amount recalled in free recall. There is a problem of interpretation here in the comparison of words with CVCs, for words may be interassociated to an extent greater than is likely to be true of CVCs. However, the correlation seems well established.

Paired-associate Learning. Learning by the paired associate method has figured very prominently in research on verbal learning since 1940 or 1950, and it has perhaps been studied more often than all the other methods combined since then. It is popular because many workers regard it as the most analytic of the methods in the sense that it supposedly allows for the study of the development of associations between one term and another one. Other investigators (see Battig, 1965, 1967), however, believe that the method involves complex processes and therefore does not permit the observation of simple associative development.

In the paired-associates method, the subject is asked to learn that when he sees or hears one item he is to respond with another one that is associated with it. For example, when one member of a pair (often called the *stimulus term* or the *left-hand term*) is presented, the subject is asked to produce the item which is the other member of the pair (the *response term* or the *right-hand member*) before this response term appears alongside its stimulus word. A list of pairs is usually employed, the pairs being presented in the sequence: stimulus member_1—pair_1; stimulus member_2—pair_2; and so on, and the subject attempts to anticipate the second member of the pair before it appears in view alongside the stimulus member. This is called the *anticipation method in paired associate learning,* and it is differentiated from serial anticipation learning by the facts that the subject never anticipates the stimulus term, that the sequence of the pairs is altered from trial to trial, and that the subject is told that he is not to learn the items in serial order. Trials are continued until the subject successfully anticipates all the response members or fulfills some other criterion.

An alternative to the anticipation method is the *study-test* or *recall* method. In this procedure, each trial consists of two parts. In part 1 the pairs are presented, and the subject

responds by pronouncing or spelling them. In part 2, the stimuli are presented alone one by one (usually in a new order), and he is asked to recall the response for each one. The anticipation method has been the more popular in recent years, but there are good arguments for the use of the study-test method (Battig, 1965).

Association value (av) and meaningfulness (*m*) have been most extensively investigated in the case of paired-associate learning. The effects of these variables have been examined with respect to the stimulus, the response, and both the stimulus and the response, that is, the pair (Underwood & Schulz, 1960, pp. 31–42; Goss, 1963; Noble, 1963; Goss & Nodine, 1965, pp. 65–110).

From the substantial amount of work that has been carried out on paired-associate learning, the following generalizations seem to hold whether meaningfulness values have been based on production or ratings and hold similarly for *av:* Pairs with an average *m* or *av* that is higher than those of other pairs are learned more rapidly than pairs with lower *m* or *av* values; learning is a function of stimulus *m* or *av,* being more rapid for higher values of these measures; learning is a function of response *m* or *av,* again being more rapid for higher values of these measures; learning seems to be more influenced by response *m* or *av* than by stimulus *m* or *av.* The literature contains occasional exceptions to these generalizations, but the weight of the evidence seems to support the generalizations for CVCs, dissyllables, and words. The experiments that have produced results that vary from these generalizations have been criticized by Underwood and Schulz (1960, p. 41) and by Goss and Nodine (1965, pp. 65–110).

Illustrative data may now be shown. In their Experiment 1, Cieutat, Stockwell, and Noble (1958) used dissyllables, scaled for *m* by Noble (1952). Separate lists of 10 pairs were set up with the patterns of meaningfulness being designated by letters. The first letter stands for the stimulus term, the second for the response term; H means high *m*, L means low *m*. Thus, we have H-H, H-L, L-H, L-L.
Figure 19.1 Learning curves for paired-associate lists in which the stimulus and response terms were high (H) or low (L) in *m*. The first letter designates the stimulus term, the second the response term. (Cieutat, Stockwell, & Noble, 1958, Fig. 1, p. 195.)
Figure 19.2. Total number of correct responses in 20 trials for paired-associate lists in which the stimulus (first-letter) or response (second-letter) varied in *m′* from High (H), to Medium (M), to Low (L). (Plotted from data reported by Cieutat, Stockwell, & Noble, 1958, Table 3, p. 199.)

Figure 19.1 shows the results for the percentage of correct responses over 12 acquisition trials for each list. The 2 curves for the lists with high-response *m* show better performance throughout than those for lists with low-response *m*, but the difference between the H-L and the L-L curves clearly shows an effect of stimulus *m*. Analysis of the data revealed that response *m* was associated with a larger portion of the variance than stimulus *m*.

In a second experiment, Cieutat, Stockwell, and Noble used CVCs with three levels of scaled meaningfulness (*m′*) for both the stimulus and response terms. The CVCs were taken from the norms for *m′* reported by Noble, Stockwell, and Pryer (1957) and were placed into 10 pair lists with the following patterns: H-H, M-H, L-H, H-M, M-M, L-M, H-L, M-L, and L-L. Figure 19.2 shows the total number of correct responses made over 20 acquisition trials. The curves are plotted for the three levels of stimulus *m′*, with the *X* axis representing response *m′*. Both stimulus *m′* and response *m′* have large effects, but the magnitude of the effects is greater for response *m′* than for stimulus *m′*, both as shown in Figure 19.2 and by statistical analysis.

Postman (1962) made up lists of paired associates composed of pairs of 2-syllable nouns. These nouns varied in the frequency of their usage in the language but also varied in *m* (Postman, 1961, Table 1, p. 100). He set up pairs in which stimulus word frequency and response word frequency varied in each case across three levels—low, medium, and high (so that *m*, which is correlated with frequency, presumably varied in the same way). For the levels of response word frequency or *m* the number of trials to criterion was 11.0, 13.6, and 14.6 as response *m* varied from high through medium to low. Corresponding values as stimulus *m* ranged from high to low were 13.2, 11.3, and 14.7. Postman has therefore found for words an effect of response *m* corresponding to effects we have described already. The irregular findings for stimulus *m* are perhaps explicable on the basis of associative interference, as is brought out elsewhere.

We can conclude, from what we have said, that *m* and *av* show strong relationships to paired associate learning. The assessments of *m* and *av* are essentially normative, however, based on responses or ratings from groups of subjects. Is it possible to develop av or *m* experimentally, that is, by having people learn varying numbers of associations to, say, CVCs, and then determining whether the CVCs differ in the rate at which they can be learned? Some attempts along these lines have been made, but it has not yet been possible to show that experimentally induced *m* has effects on learning that are independent of other, confounded variables such as induced familiarity (see Goss & Nodine, 1965, pp. 185–187, for discussion and references).

Relations of m, m′, *and* av *to Other Variables.* There are many ways in which words can be characterized, and there is often reason to anticipate that such characteristics may be related to the ease with which words are learned in verbal learning situations. Examples of such characteristics are emotionality, form class, and the abstract-concrete character of words.

With regard to characteristics of words, however, it is useful to raise the question whether they are correlated with other properties, such as *m, m′*, or *av*. To the extent that they are, our understanding of the significance for learning of matters like emotionality may be improved. This is to say that when the emotionality of stimuli influences learning rate it may be because emotionality is, in a sense, an index of *m*. If we know the nature of the relation of *m* to learning, we may require no other interpretative basis to comprehend why emotionality is related to learning.

We will discuss the relationship of emotionality to *m*, among other things, and to relational measures later. Here, however, we may point out that Epstein (1962) constructed pairs of concrete nouns, of abstract nouns, and of prepositions and conjunctions, obtaining also *m* values for the 3

kinds of words. The values were highest for the concrete words, next for the abstract words, and least for the function words. Underwood and Schulz (1960, pp. 264–267) also found for interstitial words, like prepositions, conjunctions, and personal pronouns, lower *m* values than for 3-letter concrete nouns. Epstein's subjects learned the 3 lists in an order of difficulty corresponding to the *m* values. Lambert (1955) found greater "associational fluency" for concrete than for abstract nouns, a finding replicated by Paivio (1965); the latter reported substantial correlations between *m*, ratings of words as to the ease with which words provoke sensory images, and ratings of their auditory familiarity.

Results like those described above imply that many characteristics of words are related to *m*, as well as to *m'* and *av*. In many of these experiments, the effect of *m* is probably on the associative stage of learning, that is, in the "hooking" of the stimulus to the response in the case of paired-associate learning, rather than on the response integration stage. The meaning of these notions is given in the next section.

Interpretation of the Effects of m, av, m'. Underwood and Schulz (1960, pp. 92–94) have followed the lead of other writers in suggesting a two-stage interpretation of verbal learning. The first stage is termed the *response-learning* or *response-integration stage*, in which the subject must identify the response terms with which he is to deal and, further, in the case of unlikely combinations of letters (for example, PXL), that these letters go together in a required order. The idea is that some of the subjects' learning time must be devoted to learning the composition of the responses before these responses can be linked, as in paired-associate learning, to their stimuli. The linking of responses to stimuli is the second stage of learning, referred to as the "hook-up" or "associative" stage. It is conceded, of course, that the two stages will, in fact, overlap, but for various reasons there seems to be value in postulating two stages.

One such reason, in the light of our earlier discussion, is the greater effect of response than of stimulus *m* in paired-associate learning. For this method of learning, stimuli do not have to be produced, whereas responses do. A well-integrated response, then, would be available for association to its stimulus sooner than a poorly integrated response. In verbal discrimination learning, however, neither item must be produced. Meaningfulness (*m*) has little effect in this situation. The greater availability of items with high *m* is probably shown in the influence of *m* in free recall and in serial learning.

Underwood and Schulz have suggested that *m*, *av*, *m'*, and other variables (several of which are discussed later, such as frequency of occurrence, familiarity, pronunciability and others) relate to learning scores as they do in part, at least, because they index response integration. It seems likely that the differential integration of items at the time an experiment in verbal learning is started is due to the learner's prior experience with the language. Unfortunately, it is not possible to say at present just what feature of this experience is the critical one so far as response integration is concerned.

It is very likely that *m* has effects on the associative stage of verbal learning, also. Perhaps the effect of stimulus *m* illustrates this: stimuli with many associates can be easily linked to responses (and conversely) since these associates may provide ready mnemonic ways of putting stimulus and response together. This idea, similar to the "associative probability hypothesis" discussed by Underwood & Schulz (1960, pp. 45–46) runs afoul, however, of the "interference paradox," which would arise from the proposition "that the greater number of associates, the greater the amount of interference" there would be in forming a specific S-R association (Underwood & Schulz, 1960, p. 46).

A possible resolution of the interference paradox but one which does not subscribe to the notion of associative probability has been suggested by Howe (1969). Howe has looked at data for words and non-words

(trigrams) with varying m or m' values by means of the single response free association method. He finds that m and m' are inversely related to the number of associates obtained over a sample of subjects by the latter method, that is, the high m or m' stimuli produce a relatively small number of different associates in single-response free association. However, this finding is limited to words with quite low frequencies of occurrence in printed English and to non-word low-frequency trigrams. For either multisyllabic or monosyllabic words, the relationship does not hold, if the frequencies of occurrence of the words are one in a million or higher. Thus, for certain low-frequency stimuli where m is high (or response m is high) the associative stage is easier than it is for items of low m, because there are fewer different associates to get in the way in the case of a high m stimulus than in a low m stimulus. This can be visualized if we realize that, according to Howe, the high m stimulus will have a steep slope for the frequency curve for its responses obtained by means of single-response association, whereas the corresponding curve for low m stimuli will have a more gradual slope. In the next section, we will see that the number of different responses a stimulus elicits in free association is an important variable with respect to response faults and response time and these findings, in a general way, support Howe's interpretation.

Relational measures In the production measure, we were concerned almost entirely with the sheer number of verbal responses elicited by a stimulus and it thus was sufficient to compare stimuli in terms of the number of responses they elicited or the number of people who reported an association to them. We were not concerned with what associations occurred or with the characteristics of their distributions.

Relational measures, however, are mainly used to describe the associations obtained to a stimulus or to describe the similarity in associations between two (or among several) stimuli. They represent the traditional work on the word association test, starting with Galton (1879–1880), whereas the production measures derive from Glaze (1928). In dealing with relational measures, we shall have much more to say than we did about production measures. We must give an account of (1) the distribution of associations to stimuli, (2) the conditions which influence the distribution obtained, (3) the classification of associations, (4) the measures of associative relation be-

tween or among stimuli, (5) the ideas about the character of the structure of associations, and finally, the relations between measured associational relations and performance in verbal learning tasks.

The Distribution of Associations. When many people are asked to give single-response free associations to verbal stimuli, it is commonly found that some of the responses are unique, being made by one subject only. Many responses, in contrast, are given by more than one person; some of these responses are made much more often than others. This kind of observation has been made for over 70 years (see Woodworth & Schlosberg, 1954, p. 50), but it remained for Kent and Rosanoff (1910) to test a large number of people (1,000), each of whom responded to 100 familiar English nouns and adjectives. Kent and Rosanoff listed the responses given to each stimulus word and tallied the number of subjects who gave each response. The result is a distribution of response words and their frequencies of occurrence as associates for every one of the 100 stimuli. An example is shown in Table 19.1, which exhibits the associative distribution for the stimulus word *Needle* as obtained by Kent and Rosanoff. It is noteworthy that a few responses (*thread, pin(s), sharp, sew(s), sewing*) occur in at least 100 records, whereas others, such as *pointed, cotton, work,* occur infrequently, and some (*blood, broken,* and so on) occur only once in the sample. We can speak of the most frequent response as the *cultural primary* and of the responses occurring only a single time as *idiosyncratic responses.*

Associative distributions vary in several ways. Table 19.2 shows, for 4 adjective stimuli, the response frequencies for the 10 most common responses given by a sample of 350 college students. Each stimulus has a cultural primary, but it is clear that these primaries vary in their dominance in the distributions. Thus, the primary for *Little* is *small,* at a frequency of 167 (about 48 percent of the students), whereas the primary for *Hidden* is *lost* at a frequency of only 30 (8 to 9 percent). The other primaries in the table have frequencies intermediate to these. A second difference in the distributions is their slope from high to low. In the case of *Hidden,* a graph of the frequencies for the 10 most common responses would show a gentle slope from the most frequent response to the least frequent response (from 30 to 8), whereas the slope for *Little* would be sharp (from 167 to 4). Horvath (1963) has suggested that distributions of this kind can be characterized by a parameter *a,* defined as the ratio of the number of different response words to the total number of response words. This parameter gives a quantitative expression to the slope of the associational distribution. The third difference in distributions is obvi-

ous for equal *N:* For distributions with a high-frequency primary there will be fewer idiosyncratic responses than for distributions with a low frequency primary.[3]

Another thing worth noting about the distributions shown in Table 19.2 is that two of the stimuli, *Sacred* and *Holy,* share responses such as *church, God, religion, religious,* whereas neither has any responses in common with the other two stimuli. We shall have more to say about the overlap of associations later, but the fact just summarized can be restated by saying that *Sacred* and *Holy* are associatively similar, whereas *Little* and *Hidden* are not associatively similar to each other or to *Sacred* and *Holy.*

There are available in the published literature several sets of association norms to verbal stimuli. They can be found in Palermo and Jenkins (1964), Bilodeau and Howell (1965), Entwisle (1966), and Postman (in press), as well as in earlier sources to which reference is made below. There are also many collections of norms that are unpublished and available only from the investigator who collected them. Occasional reference to these norms is made in subsequent sections (see Cramer, 1968).

The significance of distributions of associations and of associative overlap will become clear as we proceed further in this chapter. However, we may mention here a relationship that has been obtained between the frequency of responses in association tables and the reaction time for the occurrence of the responses. The importance of this relationship is that reaction time or latency is usually taken as an indication of the strength of an associative relation between a stimulus and a response. During learning of a new pair of associates the reaction time diminishes as learning progresses, and this fact, together with others, seems to justify the use of latency as a measure of association strength. Many years ago, Thumb and Marbe (1901) found that the responses made more frequently in association tests occurred more rapidly than those made less frequently; this relationship has become known as Marbe's Law. Schlosberg and Heineman (1950) verified it in a systematic study. They obtained associations and associative reaction times from 204 college students for 25 monosyllabic stimulus words from the Kent-Rosanoff set. Figure 19.3 shows the relationship they obtained between the logarithm of the latency and the degree of communality (percent of students) for each response. The correlation between these measures was −.80, meaning that on the average, a response that was given by many subjects was made with a shorter latency than was a response given by fewer subjects. This correlation has led many in-

Figure 19.3. The relationship between associative reaction time and degree of communality. Each point represents the median log reaction time of all responses that occurred with a given degree of communality. In the equation, Y is in log seconds and X is in percent. (Schlosberg & Heineman, 1950, from Woodworth & Schlosberg, 1954, Fig. 3-6, p. 65.)

[3]Another way of characterizing distributions is entropy or the uncertainty statistic (H). This has been used by Laffal (1955, 1965) and by Howe (1965), among others. This statistic is calculated by first obtaining the probability of the occurrence of each response to a stimulus, and entering probability values in the formula, $H = -\Sigma p_i \log_2 p_i$, where p_i is the probability for any given response. A response hierarchy that has a small number of different responses, with, of course, high probabilities for these responses, is one of low entropy. This measure is clearly related, then, to number of different responses and number of idiosyncratic responses given to a stimulus (Howe, 1967, personal communication). Laffal (1955, p. 268, footnote to Table 2) has suggested, on the basis of some data, that the number of different responses may be a more reliable measure of the response hierarchy than H.

vestigators to regard the relative (group) frequencies with which responses occur to word association test stimuli as representing the strength of the association between the stimuli and the responses.

Some experimental work has been reported in which association hierarchies have been established and then properties of association responses studied. Peterson (1966) presented four pairs of 0 percent association value (*av*) syllables as stimuli and paired them with words as responses. One pair was JID WUB and another JID LAJ; the two pairs were presented with *salt* and *moon*, respectively. An anticipation-paired associate method was used. In the example given, JID is paired with two responses and thus is ambiguous, whereas WUB and LAJ are paired with one response each and are thus unambiguous. (The same arrangement was used for the other two pairs.) In addition, in a block of six trials, two of the response terms were presented twice as often as the others, that is, 2 to 1, and there were seven such blocks of trials. Twenty seconds after the subject met the criterion established for this task, the individual nonsense syllables (not the pairs) were presented, and the subject was instructed to respond to each syllable with one of the words he had learned. For the unambiguous stimuli, the responses associated with them were given, in the association test, 91 percent of the time. For the ambiguous stimuli, the more frequent response was made 59 percent of the time, and the less frequent response about 30 percent of the time. Although these data show that the more frequently made response does not exclude the less frequently made one for the ambiguous stimuli, the differences are consistent with an interpretation of the frequency of occurrence in free association as being related to the prior frequency of experience of the response with the stimulus. Wiggins (1957) manipulated the number of nonsense syllable response alternatives he built into the association hierarchy for a nonsense syllable stimulus from 2 to 8, and he also varied the frequency with which he presented the pairings. After this training, his subjects responded to the stimulus syllable with the first other syllable that came to mind. His results show that associative reaction time increases as the number of alternatives increases and that reaction time decreases as number of presentations increases. The latter result is consistent with the usual interpretation of the findings of Schlosberg and Heineman, and the former result is consistent with interpretations offered by Laffal (1955) and by Davidson (1965) in other contexts, which we discuss shortly. Osgood and Anderson (1957) have presented evidence that essentially confirms the findings of Peterson.

Another matter concerning the distributions of associations pertains to the relationship between the words found in the distributions and words used generally in the language. Are responses to an association test special in any sense? It is not possible to give a general answer to this question, but Howes (1957) compared the associative frequencies of responses in the Kent-Rosanoff norms with their frequencies of usage in the Lorge magazine count (Thorndike & Lorge, 1944). When he eliminated from consideration certain words that occur with high frequency in English (conjunctions, articles, prepositions, auxiliaries, and pronouns), but which tend not to occur as associations to the nouns and adjectives used as stimuli by Kent and Rosanoff, Howes found for the remaining words a correlation of .94 between the frequency with which they were given as associates and the frequency of usage. This suggests that the associates are not a special class of words, unrelated to those in general linguistic use.

Conditions Affecting the Responses Obtained. There are a number of variables of which the responses that occur in a word-association test are a function (see Jung, 1966). They have not been investigated as extensively as would be desirable, but enough work has been done to suggest that associa-

tion strength is not the only factor that operates to cause a particular response to occur to a given stimulus.

Time pressure: In the typical association test procedure, the subject is placed under some time pressure, for he is asked to respond quickly. In some experiments, however, subjects have been asked to respond even more quickly than this, or, in contrast, they have been asked to respond without pressure. Siipola, Walker, and Kolb (1955) induced time pressure in one group of subjects and a relaxed, "time does not matter" attitude in another group. Both groups responded to 25 of the Kent-Rosanoff words. The subjects under the pressure of time responded to the stimuli that were adjectives by giving adjective responses 58 percent of the time; this percentage shrank to 35 percent under the relaxed conditions and nouns were given 62 percent of the time. In addition, contrast responses to noun stimuli appeared more often under pressure than under the relaxed conditions. Flavell, Draguns, Feinberg, and Budin (1958) compared groups instructed to respond very rapidly (one such group was rewarded with a nickel for every response made within 5 seconds) with groups given no time pressure. In one experiment they found that the group placed under time pressure produced more reactions classified as *perseverative responses* or as *distant associations* than the relaxed group, and, in another experiment which employed the same subjects under both conditions, they again found that more perseverative responses were made under the pressure of time than under relaxed conditions as well as a few other differences. Horton, Marlowe, and Crowne (1963) found that the responses given were more frequently common ones when the subject is under time pressure than when he is not.

Perhaps the only conclusion that is justified by the three studies just summarized is that pressure does have an effect on the responses obtained in an association test. Direct comparisons of the three studies do not seem warranted, for they employed different stimulus words and different procedures; they also used dependent variables that cannot be compared directly.

Stimulus characteristics: Verbal stimuli differ from one another in a great many ways, some of which might well influence the characteristics of their associative distributions. For example, the original Kent-Rosanoff stimuli were common English words, mainly nouns and adjectives. Immediately the questions arise whether uncommon words and words from other parts of speech (or form classes) will yield similar distributions. In addition, some attention has been paid to the emotionality of the stimulus words. Unfortunately, it has been difficult to ascertain the significance of any one of these factors independent of the others.[4]

The commonness or familiarity of words is usually assessed on the basis of their frequencies of occurrence in the English language according to the count made by Thorndike and Lorge (1944). Emotionality or affectivity is typically based on ratings, whereas the form class of words is identified by dictionary indications of usage, by the use of test frames (see Deese, 1963, p. 80), or by study of the use of words in sentences (West, 1953).

Shortly after 1900, the word-association test was employed as a means of determining what stimuli were emotionally disturbing to subjects. Clinical applications involved the attempt to diagnose "complexes" in terms of the stimuli to which disturbed responses occurred, and there were also attempts to detect "guilty knowledge," again by means of disturbed reactions to stimuli, which were known to represent aspects of a situation a guilty person would know about but an innocent person would not. This work has

[4]In this discussion, the writer has relied on part of the book by Phebe Cramer (1968), to whom grateful acknowledgment is made for the privilege of seeing the manuscript prior to its publication. Dr. Cramer has also provided a bibliography of over 300 titles concerned with word association tests. (See also Skilling, 1962.)

been summarized in the earlier editions of this book (Woodworth, 1938, pp. 363-367; Woodworth & Schlosberg, 1954, pp. 66-71) and because the area has not been an active one for investigation since then it will not be treated here. However, see Cramer (1968), Rapaport (1951), and Rapaport, Gill, and Schafer (1946). Such uses of the word-association test imply that features of the association response distribution are influenced by the affective or emotional character of stimuli.

The criteria of associative disturbance or of response faults made to stimulus words usually include delay in making the response (prolonged reaction time) and failures by a subject, on a second run of the same association test, to reproduce, when he is instructed to do so, the response he gave to the stimulus the first time through. Laffal (1955) employed these criteria, and others, in evaluating the responses of 80 subjects to 100 stimulus words, but he also examined other properties of the response distributions to determine whether variables other than emotionality were correlated with the occurrence of disturbances to the stimuli that produced them. Laffal found that response faults were made mainly to stimuli that have many different responses in their associative distributions and that they occur less frequently to stimuli with fewer responses in the distribution. (A measure of response entropy for the distributions yielded the same result.) He concluded that response faults do not necessarily indicate that the stimuli to which they occur are emotional ones or arouse emotional reactions.

Laffal did not obtain information concerning the emotionality of his stimulus words, and it remains a possibility that emotional stimulus words have the characteristic of producing a greater number of different responses than do neutral words, other things being equal. Cramer (1965) gave a word-association test composed of 20 traumatic and 40 neutral stimulus words to college students and to schizophrenics. She found that both groups gave a greater number of different responses to the traumatic than to the neutral words but that the Thorndike-Lorge frequency of the words was not significantly related to the number of different response words for either group. Brown (1965) found differences between neutral and emotional words even though the two sets of items did not differ significantly in the number of unique responses (closely related to number of different words) they elicited; the differences Brown found pertain mainly to indicators such as repeating a previous response, repeating stimulus words, forgetting (or remembering incorrectly) the response given to the stimulus on the previous testing, and elongated reaction time. On all of these measures, there were more response faults for emotional than for neutral stimuli.

It appears to be legitimate (see Cramer, 1968) to conclude that the emotionality (mostly negative) of stimulus words is associated with response faults and with a greater variety of responses, at least for single-word association tests. There is evidence, however, that in multiple-response association procedures, neutral stimuli may elicit the same number of responses as emotional stimuli (Koen, 1962). This suggests that somewhat different processes may be involved in the procedures, the single-response measure perhaps getting at the most available responses, the multiple-response method getting at the associative repertoire.

There is some tendency for the responses given to affective stimuli to have affective characteristics similar to those of the stimuli (Cramer, 1968). Pollio (1964) compared the semantic differential ratings (see the section on rating methods) for 52 Kent-Rosanoff stimulus words with the same ratings for their primary associates. The correlations ranged from .52 for the evaluative factor to .36 for activity and .26 for the potency factor; higher correlations than these were obtained for 38 stimuli and their primaries from norms for children (Woodrow & Lowell, 1916). Pollio also computed parallel correlations (for adult norms) for stimulus words with high-fre-

quency primaries (probability of .65) and words with low-frequency primaries (.26). The correlations between the semantic differential ratings for the stimuli and the low-frequency primaries ranged from .41 to .66 for the three factors that the semantic differential analysis yielded but for the cases of the high-frequency primaries the correlations were zero. This suggested to Pollio that meaning, as measured by the semantic differential, is involved in the selection of associates as low-frequency primaries, whereas word-word habits (such as table-chair) are involved in the high-frequency primaries. Pollio also found, in a separate analysis, that strongly negatively evaluated stimulus words elicit association responses that are considerably less negative than the stimuli themselves; positively evaluated stimuli, however, tended to elicit positively evaluated responses (see also Pollio & Lore, 1965, and Staats & Staats, 1959).

Howe (1965) compared features of the associative distributions for 58 words with a composite value (D_4) for their rated deviation from neutrality on the semantic differential (see Jenkins, 1960). The associative measures he used were an uncertainty measure (see footnote 3), the number of different responses in the distribution, the frequency of the primary response, and the frequency of idiosyncratic responses. Twelve of the stimulus words were "bad" words, that is, evaluated negatively on the semantic differential, and the rest were "good" words. Howe found moderately high correlations (.406 to .682) between D_4 and the four associative measures for bad words and similar correlations for the good words, which are highly polarized (high D_4 words), but none for the good words of little polarization. The separate factors of evaluation and activity, however, also correlated with the associative measures, leaving some uncertainty about the importance of the correlation of these variables with D_4.

Pollio (1963) developed evaluative reactions to nonsense syllables by the following procedure. One syllable was paired with nine words (one at a time) such as *music, comfort,* or *beautiful,* all of which are positively evaluated on the semantic differential; a different syllable was paired with nine negatively evaluated words (for example, *sickness, anger, afraid*), and a third with nine neutrally evaluated words (for example, *boulder, glow, run*). Suitable balancing of syllables with word sets was carried out. Following these pairings, each subject was asked to give associations to the nonsense syllables on which he had been trained; the associations thus given were rated by other subjects on the evaluative scale of the semantic differential. Pollio found that the associates, whether they were words that had been paired with the syllables or not, were evaluated as positive if the syllables had been paired with positive words, negative if the syllables had been paired with negative words, and so on. This is an experimental confirmation of the conclusion made earlier: The association responses are affectively similar to their stimuli.

It has sometimes been proposed that the familiarity or the frequency with which a word occurs in the language has an influence on the association response distribution. Hall and Ugelow (1957) obtained single-response free associations to 48 words, half of which had a high frequency according to the Thorndike-Lorge list, while the other half were low frequency words. They determined the number of different words given for each stimulus word by their 40 subjects and divided this number by the total number of words given to it. The ratio so obtained for the high-frequency words was .381, whereas for the low-frequency words it was .642. This result means, of course, that relatively fewer different responses were obtained for high-frequency than for low-frequency words. Cramer (1968) has observed that this same relationship has been obtained by Postman for a sample of 1,000 college subjects and a larger sample of stimulus words. (Postman, 1964, reports briefly some features of these data, not including those mentioned by Cramer.)

There is evidence, however, that runs con-

Stimulus word	*Response before practice*	*Time (sec)*	*Response after practice*	*Time (sec)*
Bank	building	2.6	England	1.8
Axle	hub	2.2	grease	1.2
Spread	distance	3.4	bed	1.4
Sister	Anna	5.0	brother	1.4
Suffer	weak	2.2	pain	0.8

trary to this inverse relationship between stimulus frequency and the number of different responses (Veness, 1962; Cramer, 1965). Cramer (1968) has suggested that in some studies of this relationship the factor of emotionality has been confounded with that of familiarity or frequency, that is, that high-frequency stimuli tend more often to be neutral than low-frequency stimuli. Because emotional stimuli produce a greater variety of responses than neutral ones, this could produce the inverse relation obtained between frequency and number of different responses. However, Cramer does conclude that there is a slight inverse relation between stimulus frequency or familiarity and number of different responses which occur to verbal stimuli.

Another factor that is involved, however, is the form class of the stimuli. By *form class* is meant, essentially, the part of speech of a word, that is, whether it is typically a noun, verb, adjective, and so on. (Many words, of course, are found in more than one form class.) For adjectives, Deese (1962) found that responses of the same form class as the stimuli are made when the adjective stimulus was high in Thorndike-Lorge frequency, but not otherwise. For stimuli in other form classes there was no relationship between the form class of the response and the frequency of the stimuli.

In two studies, the Thorndike-Lorge frequency of the responses made in continued association was found to be positively related to the frequency value of the stimuli to which the responses were made (Johnson et al., 1965; Schulz & Thysell, 1965).

From the material we have just reviewed, it appears that characteristics of the word associations obtained are or may be influenced by the emotionality, the familiarity and the form class of the stimuli. A fully adequate assessment of these relationships must await the conduct of further investigation.

Practice and instructional conditions: Wells (1911) investigated the effects of practice on word-association performance. He tested each of his six subjects with 50 words each day, using new words each day, over 20 consecutive days. On the two following days he repeated the lists employed on the first two days. Wells found that the average reaction time declined over the 20 days from about 1.75 sec to 1.2 to 1.3 sec, despite the fact that different stimuli were being used each day. Quite obviously, the reduction in latency could not have been due to practice on specific associations. The minimum reaction times obtained each day remained throughout at 1.2 seconds, but long reaction times tended to drop out with practice. On the repetition of the first two lists after this practice, Wells found results like those shown at the top of the page for five stimulus words.

The changes in responses have been said to show that, with practice, the responses become more superficial; what is meant here is that the response appears, with the stimulus, to complete a phrase (*Bank of England, axle grease*) or to make a common pair (*sister-brother*), or the response has a sound similar to that of the stimulus (*spread-bed*). If these responses are, in some sense, "easier" to make than are those to the same stimuli at initial testing, it may be that this kind of change accounts for the reduction in reaction time with practice. Some parallels may be

noted in these results with those obtained under time pressure.

Training of a somewhat different kind has been studied by Maltzman, Bogartz, and Breger (1958) and by Maltzman, Simon, Raskin, and Licht (1960). In many of their experiments, the basic conditions were (1) the administration of a 25-item free association test (training list) and (2) the administration of a second, similar test (test list). Between these two test administrations a variety of training procedures was employed. The interest of these investigators has been concerned with the effect of this training on the originality of responses to the second test. (Originality here is defined as the mean frequency of the responses given by each subject, the frequencies being based on normative data for the lists.)

In one experiment (Maltzman et al., 1960), two control groups were used. One simply took the training and test lists in sequence. The second took the training list and then retook it five times, each time attempting to repeat the response to a given stimulus that each member of the group had made before. Then the test list was administered. Two experimental groups responded associatively to 125 new words between the training list and the test list, one set of new words being of high and the other of low frequency. Finally, a third experimental group took the training test and then retook it five times, each time attempting to give a different response to each stimulus. Then it took the test list.

The scores of the two control groups showed an increase in originality on the test list, relative to the training list.[5] However, the three experimental groups showed much larger increases in originality on the test list. Comparable results have been reported by these investigators for the training condition in which the training list is repeated several times with the subject attempting to give a new response each time, although various other training procedures were not successful. Gallup (1963, Experiment 3) has not replicated these findings, and the reasons for the failure are not at all clear (Maltzman & Gallup, 1964).

Maltzman and his coworkers (1958, 1960) have also analyzed the changes in the number of idiosyncratic or unique responses given to the stimuli of the training list when it is repeated five times (after the initial testing) under the instructions to give a different response each time to each stimulus. The percentage of unique responses changes from about 10 on the first testing to about 70 on the sixth testing (Maltzman et al., 1960, Figure 1, p. 4), a result confirmed by Caron, Unger, and Parloff (1962-1963).

On the basis of the information available, it is not possible to compare the findings reported by Wells (1911) with those reported by Maltzman, for Wells's characterization of changes in the kinds of responses arising from practice did not include the measurement of originality. Nevertheless, it is clear, from these studies, that successive presentations of the same or different lists alter the characteristics of responses found on a second list and on the same list when it is repeated.

In the study already mentioned, Maltzman and his coworkers (1958) included a condition in which after responding to the training list the first time, and, where appropriate, during the repetitions of this list, students were asked to respond to the test list by being "as original as possible on the new list of words." Again, scoring the responses on the basis of the norms for frequency, Maltzman and his coworkers found a mean of 7.61 for the control subjects given instruction and one of 23.98 for subjects that had not been given instruction (the lower the value the more original the responses); similar differences were found for the two experimental groups that had responded with different responses to each of the five presentations of the training list. Clearly, these instructions had a powerful effect on the originality of associations. The reverse procedure was followed

[5]Maltzman & Simon (1959) found this effect to be a function of time between testings.

by Jenkins (1959), who, after giving the association test once, administered it again later (after 5 min or one month) under the instructions to "make the response that other college students would make." For both time intervals, the number of primary responses increased at the second test, and the frequency of the primary increased for 89 of the 100 items. Jenkins also found that subjects who, on test one, infrequently gave primary responses showed a vastly greater increase in such responses under the "popular instructions" than did those whose records on the first test showed many primaries (see also Horton et al., 1963). Kjeldergaard (1962) also increased the number of primaries on the Kent-Rosanoff test by asking his subjects to give opposites as responses where possible; this result is understandable when it is realized that the primary responses for many of the Kent-Rosanoff stimuli are opposites.

To evaluate the hypothesis that subjects might instruct themselves to respond in given ways, Jung (1966, p. 131) tested them in pairs after instructing them to give their responses aloud. There were five repetitions of a list of 10 stimuli, but each subject was given a different list. The subject in each pair who responded second was given written free association instructions, but half the subjects who responded first were told to give the same response each time the same stimulus appeared and the other half were told to give different responses. Jung found that the number of different responses given by the second subjects reflected the instruction given the first subjects. This kind of finding probably indicates that the second subjects were modifying their behavior (self-instruction) on the basis of what they heard the first member of the pair say. This may be an example of a "set" to respond in a given way. Usually, however, sets are not engendered so directly, that is, a means more indirect than instructions is employed. For example, Jung (1966, p. 128) led subjects to think that an association test either was a measure of creativity or of social adjustment. Subjects responding under the former set gave a greater number of different and less common responses than those functioning under the adjustment set to the same stimulus words. We shall see what is also probably the same thing as set when we examine the effects of context on responses to the stimuli of association tests.

Controlled association: When instructions are used that limit the kind of response a subject may give on the basis that the response must bear some kind of relationship to the stimulus (for example, opposite, synonym), we have controlled association (see p. 851). The characteristics and processes of controlled association have long been of interest to students of thinking (Humphrey, 1951) and other processes involving response selection. Where evidence for response selection exists, the important question concerns the mechanism by which the selectiveness is achieved.

The main emphasis in the study of controlled association has been on association latency because, under the conditions in which latencies are measured (individual testing, with responses given aloud), very few responses occur which are incorrect, that is, inappropriate to the stimulus in relation to the kind of response required by the instructions. It has usually been concluded that responses under controlled association are given quickly, typically somewhat more so than is the case with free association.[6]

Baker and Elliott (1948) investigated the question of the time for the occurrence of free and controlled associations in circumstances which provided that the same response would occur under each set of instructions. They selected stimulus words that had opposites as high-frequency responses. To half of these words subjects gave free associations and then to the other half they responded after being told to give opposites. For another group, the sets of words were reversed, although free associations were

[6]See page 56 ff. in the 1954 edition of this book for a summary of this literature.

obtained first. Baker and Elliott found that associations were given more quickly under the instructions to give opposites than under free association instructions, despite the fact that identical responses occurred in both conditions. (They found similar results for part-whole associations.) A possible objection to this conclusion, that the faster controlled association times might have been due to the practice afforded by the prior free association procedure, was overcome in an unpublished experiment by E. H. Davidson and the writer. Independent groups of subjects were used for the two instructional conditions, and the results paralleled those reported by Baker and Elliott.

An extensive study of controlled association has been reported by Davidson (1965), and it is possible to make some interpretations of the process of response selection on the basis of his investigation. Davidson used three lists of 10 words each; one was composed of stimuli the primary free associations of which are opposites, the second contained stimuli that elicit synonyms as primaries, and the third stimuli the primaries of which are words other than synonyms or opposites. Twenty-one groups of 27 subjects each were used, and each stimulus list was presented to independent groups under one of seven instructional conditions. The conditions were as follows: To give (1) opposites, (2) synonyms, (3) opposites *or* synonyms, (4) free associates, (5) any word *except* an opposite, (6) any word *except* a synonym, (7) any word *except* an opposite or a synonym. From normative data, it was known that, for all the stimuli employed, opposite, synonym, or other word responses were possible, although the words differed, as indicated, in terms of their primaries.

Most of the responses Davidson obtained were appropriate to the stimulus under the given instructional condition. His results indicate that controlled association times are not always shorter than free association times. For example, the mean latency of the response to the stimuli with opposites as primaries was 1.09 sec when the free associations obtained were the normative opposite primaries, and was 0.99 sec for the same responses if instructions were given to state opposites. This difference is in the same direction as that reported in the literature but is not significant. The same comparison made of the responses to stimuli whose primaries are synonyms (primary responses only) yielded latencies of 1.35 sec under free and 1.47 sec under controlled association instructions. This difference was not significant, but it is the reverse of that expected from the literature.

However, responses under conditions of controlled association were made more slowly than under conditions of free association when the restriction involved giving a response *other than* or *except* some response. For example, in the case of stimuli whose primaries are opposites and with instructions to make any response except a synonym (which, of course, permits the opposite primary), association latency increased to 1.24 sec, as compared with 1.09 sec, a significant difference. If words with other word primaries are used and the instructions are given to make responses of any word except an opposite, an average latency of 1.50 sec was obtained; if the instructions were given to state any word except a synonym, a latency of 1.49 sec, was obtained; this may be compared with the latency of 1.32 sec if the same responses were requested under conditions of free association. Clearly, certain kinds of response restriction conditions lengthen, rather than shorten, associative latencies. Other findings reported by Davidson are consistent with this finding.

Davidson also examined the free association frequencies of all the appropriate responses and found a correlation, across all association conditions, between the logarithm of association frequency (%) and the latencies of these responses of $-.83$, indicating that the more frequently made responses (in free association) occurred more rapidly, across all of the association condi-

tions of his experiment, than the infrequent responses. A parallel finding emerged in terms of the number of responses in the free association hierarchy which had higher free association frequencies than the one given (and correct) in the conditions of Davidson's experiment. The correlation between this value and the association latencies was .81. (Both measures, frequency in free association and number of more frequent responses, intercorrelate at −.88, so both are measures of the same variable.)

These results suggested to Davidson a model of controlled association of the following kind. Given instructions and a stimulus, a subject scans his free association hierarchy for that stimulus to find a response which matches the instructional restrictions for that stimulus. If the desired response is high in the hierarchy, the subject can find it after a short time; if it is not high, responses that are high must be rejected and the search continued until the appropriate response is found; this takes time. That association frequency or number of competing responses is not the whole process, however, is indicated by the lengthening of the latency that occurs, for example, when an opposite is given to a stimulus with an opposite as its primary even when the instructions were to give any word *except a synonym*. The prolongation of the latency here may be due to the necessity of deciding whether the high-frequency opposite is not a synonym. Baker and Elliott's opposite primaries had a mean frequency of 88.1 percent, whereas Davidson's parallel stimuli had primaries with a mean frequency of 55.5 percent. It may be that the very high frequency of the former primaries permitted them to occur so quickly and to be matched according to the instructional requirements so quickly that their latencies were shorter if the subjects were given instructions to give opposites than they were if they responded under free association conditions. Perhaps free association conditions induce some degree of uncertainty as to the proper response to give, a condition not present with Baker and Elliott's high frequency opposites when subjects were under instructions to give them.

Under some conditions, controlled associations are not as appropriate as it has been indicated that they are in the experiments involving latency measurements. Cofer (1967) obtained data for four controlled association conditions by administering tests, on printed forms, to one group at one time. Thus the subjects remained anonymous and, of course, were not subject to an evaluation of their responses as they gave them. Responses inappropriate to the stimulus word under the instructions given were made with considerable frequency under these conditions. Furthermore, there was evidence indicating that the more frequent a response was in the free association distribution to a stimulus, the more likely it was to occur inappropriately to that stimulus in controlled association. The matching of responses against instructional requirements under these conditions appears not to be so careful or precise as it is in conditions like those used by Davidson.

Cofer also compared the responses obtained for the same stimuli under free and controlled association conditions and found a marked overlap in the responses occurring under free association and each of his controlled association conditions. This suggests that the restrictive instructions of controlled association lead to a selection from the large pool of responses that are available or are somehow related to verbal stimuli and which appear in free association hierarchies.

Contextual conditions and priming: Stimulus words cannot be presented for free association in isolation from all other words, so that the factor of context, that is, the other items in which a stimulus word is embedded, undoubtedly influences the responses obtained. There is no way to eliminate context entirely, so determinations of the effects of context involve comparisons of one contextual situation with another. Several approaches have been used.

One way to detect the effects of context

is to determine whether responses obtained in a word-association test are determined by the order in which the stimuli are given in the test. Wynne, Gerjuoy, and Schiffman (1965) employed a stimulus list composed of 54 of the Kent-Rosanoff stimuli, for 24 of which (A-items) the primary response is an antonym. They arranged three orders of the 54 stimuli such that in one order (List 1) the first nine items and 12 of the next 30 were A-items. In the other two orders the A-items were dispersed more widely through the set; in List 2 they were fairly evenly distributed but with four of the first nine being A-items, whereas in List 3 no A-items occurred in the first nine but were concentrated in the last 15 items. Lists 1 and 2 produced significantly more antonym responses than List 3, this effect presumably being due to the context of from four to nine A-items among the first nine of the list. Similar differences were also obtained between Lists 1 and 3 under different instructional conditions (see also Carroll, Kjeldergaard, & Carton, 1962). These findings indicate that norms of word associations are affected by the context within the list, and thus it would seem to be advisable to use a variety of orders of items for different subjects in collecting further word-association norms.

Another way of studying the effect of context on the word associations obtained is to present a stimulus in the context of one or more other words, that is, as a component of a compound. When this is done, interest focuses either on the frequencies of specific words made as responses to the compounds or on characteristics of the entire distribution of associations to the compound, as compared with the case for one or the other of the individual components of the compound (see Cofer, 1967).

Howes and Osgood (1954), for example, were interested in the responses *bad, evil, fear, fright, frightening, gloomy, hell, mysterious, scared,* and *scary* as they were made to the stimulus *Dark* presented either in a neutral context or presented in the context *Devil, Fearful, Sinister, Dark.* Their subjects were instructed to listen to the entire compound but to respond to the terminal word (in this case, *Dark*). The frequencies of the occurrence of the responses of interest were augmented by the context just indicated, as compared with the neutral context (numbers or nonsense words). Rouse and Verinis (1965) replicated this finding, augmenting the frequencies of specific primaries by using as context for the stimulus items words which tended to define the response word or tended to go with it in English. For example, *town* is the primary response of the stimulus *City;* the frequency of town was augmented when the stimulus was made *Small City.* When *city* is modified by *small*, the compound is almost definitive of the response, *town.* Further, small often occurs in the language with town, as in the phrase, *small town.*

Cramer (1964) has studied "indirect priming"; the operations she has used are very similar to those employed by Howes and Osgood. In Cramer's experiments, a specific word is chosen, and the contextual arrangements are designed to influence this specific response. For example, the words *Moth, Bird, Eagle,* and *Spider* each elicits the response *fly* when they are used as individual free association stimuli in single-response free association tests. Cramer's procedure was to present the context *Moth, Bird, Eagle,* and then the stimulus word, *Spider.* She found augmentation of the response *fly* under these conditions, as compared to the frequency with which it was made as a response to the stimulus *Spider* alone. Cramer also found other arrangements of context that did not augment the frequency of the target word (see Cofer, 1967, for a discussion of possible factors in the successful and unsuccessful instances in Cramer's work).

Jenkins and Cofer (1957) and Rouse and Verinis (1965) have observed that the distribution of responses made to compound stimuli is often very different from those obtained for either component alone. For example, responses to the compound, *Thirsty Girl,* were more scattered, that is, the response

frequency distribution was flatter, than it was to the stimulus, *Thirsty* or *Girl*, alone. It appears likely that the effects of context on specific association responses and on the distribution of associations will vary markedly with the kinds of context used and the relationships among the components and between each of them and target responses. When prediction formulas have been used in attempts to forecast the frequency of a response to a compound on the basis of the frequency of that response as a response to each of the components, predictive accuracy has sometimes been good (Podell, 1963) and sometimes poor (Cofer, 1967).

From what had been said about stimulus compounding and indirect priming, it is clear that context can have a powerful influence on associative behavior. Unfortunately, to date, no clear principles have emerged in terms of which positive and negative effects can be conceptualized.

Another form of contextual influence has been named *direct priming*. This influence can be illustrated by examples studied by Storms (1958; see also Clifton, 1966). The response word, *eagle*, occurs in free association at a frequency of 1 percent as a response to the stimulus *Bird*. Suppose now that *eagle* is embedded in a list of words to be learned prior to the administration of an association test in which the stimulus *Bird* occurs. The frequency of *eagle* as a response to *Bird* under these conditions is 10.2 percent, a significant increase. Direct priming of associations has been studied fairly extensively (see Cofer, 1967), but, again, all the principles that govern whether or not it will occur have yet to be identified. At a gross level, however, direct priming illustrates again the powerful influence of context on association test behavior.

Multiple-response and single-response tests: When multiple responses are made to stimuli, it is of some interest to compare the resulting response distributions with those obtained for the same stimuli by the single-response method. Rosen and Russell (1957) presented each of 100 association test stimuli twice in succession, asking their subjects to respond to the second presentation with a word different from the response given the first time. The second response, on the average, was one of lower normative frequency than the first one. For 15 stimulus words the median rank-order correlation for the second responses which occurred more than once with their ranks in the cultural norms was 0.75; this suggests that there is some similarity between the hierarchies obtained under single- and multiple-response conditions. A similar conclusion was reached by Cofer (1958), who obtained continued associations for 25 stimulus words, on which there were also single-response norms, from 48 subjects. The primary response for 16 of the 25 words was the same word when either method was used; six other primaries given as responses under the single-response conditions were among the 10 most frequent responses given to the appropriate stimuli under the multiple-response conditions. Cofer computed the median single-response ranks for the words in the top 10 ranks in frequency for the multiple-response data. The median single-response rank for his highest ranking responses (across 25 words) was 1.28, and for his responses with ranks 2, 3, 4, and 5 the single-response ranks were 3.21, 6.00, 6.96, and 9.25, respectively. These relative correspondences led Cofer to conclude that the methods produce roughly comparable hierarchies, expecially considering the possibility that the ranks assigned to responses below the first two to four ranks are probably not very reliable for either method.

Laffal and Feldman (1962; see Laffal, 1965) have analyzed word-association responses in terms of the categories that the responses represent. For example, words like *huge* and *tall* are allocated to the category *Big*, and words like *table, chair, lamp, couch,* and *furniture* are classified in the category *Household* (see Laffal, 1965, Appendix 1, for an extensive description of the categories and their use in scoring association responses). Laffal and Feldman found by means of factor

analysis that the structure of word categories for the single- and multiple-response methods is substantially the same. This indicates further support for the conclusion implied above that multiple-response methods yield hierarchies for stimulus words that are much like those generated by single-response methods.

There is interest, of course, in whether the hierarchies of association responses obtained from groups of subjects are also indicative of the relative strengths of responses in an individual's repertoire. The data of Rosen and Russell (1957), limited as they are to the first two responses, support the conclusion of a considerable resemblance. (We shall have a little more to say about this later.) Cofer's and Laffal's data, however, do not bear on this issue (Karen Stark, personal communication).

Subject and cultural variables and cultural change over time: The *word-association test,* almost from its inception, has seemed to afford a way to study personal characteristics and, thus, differences among individuals. Indeed, Galton (1879–1880) stated, referring to his own associations, that "They lay bare the foundations of a man's thoughts with a curious distinctness, and exhibit his mental anatomy with more vividness and truth than he would probably care to publish to the world." We mentioned above the early interest of clinicians in word associations as a means for detecting "complexes," although clinical interest in word-association tests has not been a major impetus to their use for some time. Nevertheless, there are scattered findings of relationships between word-association responses and individual differences, and there is evidence concerning cultural differences and cultural changes in word associations. Furthermore, it is of interest to inquire whether normative word associations adequately reflect the individual's own association hierarchy. The individual differences that have received the most attention are those having to do with sex, age, and personality characteristics and styles.

Mandler and Parnes (1957) found striking individual consistencies in the number of continuous association responses given to both verbal and nonverbal stimuli; the subjects were likewise fairly consistent in the proportion of idiosyncratic responses they gave. Jenkins (1960) has distinguished people on the word-association test on the basis of the number of responses they make that are popular ones (that is, primaries in group norms); there is a wide range of variation in this commonality score over groups of subjects, and it is a consistent trait. Tested with the same stimuli on more than one occasion, the subjects showing a high commonality tend to repeat the same responses and continue to make high commonality scores; subjects showing low commonality tend to vary their responses from occasion to occasion, still giving uncommon responses (Jenkins, 1960, p. 312). Carroll, Kjeldergaard, and Carton (1962–1963), however, have shown that a large portion of this commonality score comes from stimuli that frequently elicit opposite responses. This may account for the failure of the commonality score to relate well to other individual differences, aside from other association tests (Jenkins, 1960).

Girls and women yield somewhat higher commonality scores than men (Palermo, 1963, p. 43; Jenkins & Russell, undated). Also Palermo and Jenkins (1965a) found that female college students made significantly higher frequency primary, secondary, and tertiary responses to 200 word-association stimuli than did males. Another variety of sex difference was studied by Goodenough (1942, 1946), who developed a test using homographs with more than one meaning as stimuli. Thus, *bow* can be a ribbon for the hair or a device with which to shoot an arrow, the former being perhaps a "female response," the latter a "male response." Goodenough was able to differentiate reliably between male and female subjects on the basis of the content of their responses to a set of such homographs.

There is evidence for shifts of associative responses with chronological age. For exam-

ple, Kent and Rosanoff (1910), for a sample of 1,000 men and women, found the following primaries for the stimuli *Table, Dark, Man, Deep, Soft: chair, light, woman, shallow, hard.*[7] For children, however, Woodrow and Lowell (1916) found these primaries: *eat, night, work, hole, pillow.* One characteristic of the responses of the children is that they would easily follow the stimulus word in ordinary language, for example, *Dark-night, Deep-hole, Soft-pillow; Table-eat, and Man-work* would seem to involve a verb as the response to noun stimuli. The responses of the adults, however, to these five stimuli would not ordinarily occur with their stimuli in the language (without an intervening word), for example, *Dark-light, Soft-hard,* and *Table-chair.* The responses in each case belong to the same form class as the stimulus, that is, *Table* and *chair, Man* and *woman* are usually nouns, and *Dark-light, Deep-shallow,* and *Soft-hard* are usually adjectives.

Ervin (1961) obtained free associations from children in kindergarten, the third and sixth grades and classified their responses to 30 stimulus words according to whether they belonged to the same form class as the stimulus and whether they would *not* follow the stimulus in sequence in ordinary continuous speech. (Responses meeting these two criteria are called *paradigmatic associates.*) She found that the proportion of paradigmatic responses tended to become greater over the age range of her subjects. Thus, for eight noun stimuli, the kindergarten subjects gave on the average 50 percent paradigmatic responses, whereas the third grade gave 73 and the sixth grade 76 percent (calculated from Ervin, 1961, Table II, p. 367). Similar changes were observed for responses to verbs, prepositions, adverbs, pronouns, and comparative adjectives (see also Brown & Berko, 1960; Palermo, 1963, Table X, p. 55; Entwisle, Forsyth & Muus, 1964). Paradigmatic responses were made with increasing frequency by the children in the first three grades of the Paris Municipal Schools (Rosenzweig & Menahem, 1962).

[7]The same primaries again were obtained by O'Connor (1928).

The increase in the proportion of paradigmatic responses with age has been reported (see references above) to be accompanied by a decline in syntagmatic responses, that is, responses which can easily follow the stimulus in ordinary speech (for example, *Deep-hole*). Although the trends we have indicated are well documented, they are subject to two qualifications. For one thing, the sample of stimuli used in most of these studies has been relatively limited. The other is that cultural changes can apparently alter the age and the course of the shift from syntagmatic to paradigmatic responses.

The first of these points has been made by Deese (1962), and the data reported by Fillenbaum and Jones (1965) agree well with his. Deese obtained free association responses from 100 male college students to 600 English words. The words represented a wide range of Thorndike-Lorge G-count frequencies: 253 nouns, 118 adjectives, 101 verbs, and 32 adverbs were used (the remaining 96 words were not analyzed for several reasons). Using this set of stimuli, Deese found the percent of paradigmatic responses to be 78.6 for noun stimuli, 51.9 for verb stimuli, 51.1 for adjective stimuli, and 27.2 for adverbs. (The high-frequency adjective stimuli yielded a high proportion of paradigmatic responses, whereas the low-frequency adjective stimuli produced a predominance of syntagmatic responses.) These results suggest that paradigmatic responding in adults is the rule for noun stimuli and for high-frequency adjective stimuli but that it is barely dominant for verbs and not at all dominant for adverbs and low-frequency adjectives. Deese's values may be compared with those reported for twelfth-graders by Palermo (1963, Table X, p. 55), whose value for nouns is 71.2, for adjectives 42.2, for verbs about 37, and for adverbs 44.2. The large discrepancies for verbs and adverbs may be due to the differing numbers of the stimuli in the sets used by Deese and Palermo.

The other limitation came to light when Jenkins and Russell (1960) compared norms from about 1,000 college students for the 100 Kent-Rosanoff stimuli obtained at the University of Minnesota in 1927 and again in 1952. Finding certain marked changes in these sets of data, they also made comparative studies with other norms collected elsewhere in 1910, 1925, and 1933–1934. The average frequency of the primaries for the two Minnesota samples showed an increase between 1927 and 1952 from 267.5 to 377.5, and there was also an increase in the frequency of the second response, from 111.9 to 137.1. However, 71 percent of the primaries in the 2 sets of norms were identical, and 22 of the remaining primaries in 1927 had shifted to either the second or the third rank by 1952. The response primaries that dropped in frequency between 1927 and 1952 tended to come from superordinate pairs (for example, *Red-color, Sheep-animal*) or from synonym pairs (for example, *Sickness-illness, Comfort-ease*) and to be replaced by more specific and concrete responses or by pairs indicating a sequential relation (for example, *Red-white, Sheep-wool, Sickness-health, Comfort-chair*). Other data from college populations agree with the trend to an augmented frequency of primaries over time, and the identity of primary responses is greatest for norms collected nearest in time to each other. The decline in the occurrence of superordinate responses also was confirmed in the comparisons of other norms. Jenkins and Palermo (1965) have analyzed additional evidence that tends to support the trends described by Jenkins and Russell, and Palermo and Jenkins (1965b), comparing norms for fourth- and fifth-grade Minneapolis school children obtained in 1916 and 1961, found increases, over this time period, for the frequencies of popular responses, of paradigmatic responses, and of contrast responses, among other changes.

Cultural changes, then, must be taken into account with respect to comparisons of groups differing, for example, in age. The prevalence of the syntagmatic response in children, true in 1916, is no longer so prevalent in 1961.

In conjunction with cultural changes, it is worth mentioning that some attention has been paid to occupational and nationality variables in word association. Rosenzweig (1961) has made comparisons of word-association data collected with the Kent-Rosanoff stimuli in several countries—France (Rosenzweig, 1957), Germany (Russell & Meseck, 1959), and Italy (unpublished data made available by Mario Levi); the data for American English were from the Russell-Jenkins (1954) norms. In general, the primaries obtained in the four languages agree fairly well, best agreement across languages being obtained for the highest frequency primaries. The frequencies with which the primary responses are given tend to be substantially higher in the United States than they are in the European countries studied. Foley and MacMillan (1943) studied associative responses of students in medical school and in law school using words that have different meanings in the two professions but which are spelled alike. For example, the word *administer* is used differently in law and medicine; the medical students responded to it with words like *dosage, sick,* and *attend,* the law students with words like *estate, govern,* and *justice* (see also Murphy, 1917). Other differences between occupational groups occur but may be confounded with other characteristics of the groups, such as education (see Rosenzweig, 1964).

A number of studies have been carried out to explore possible relations between characteristics of personality and features of word association (see Nunnally & Flaugher, 1963). Many of these have offered suggestive findings, which have not, however, been followed up. Consequently, we restrict our discussion here to investigations that have stressed the presence of "styles" of response to word-association tests.

Dunn, Bliss, and Siipola (1958) employed instructions which relaxed the pressure of time. As Siipola and her coworkers (1955) had

previously shown, however, under these conditions subjects still vary, some subjects setting a fast tempo of response for themselves, others responding in a leisurely manner. Associated with these response tempos are differences in the kinds of responses which occur and in the amount of imagery which each subject can report as having been involved in the generation of the response to the stimulus. Thus, the subjects who responded quickly tended to give contrast responses and report little imagery, whereas the others concentrated on noun associates to adjective stimuli and report complex processes intervening between a stimulus and the response. Dunn and her coworkers were able to show that subjects classified as impulsive by a personality test responded significantly more quickly, gave more contrast responses, and displayed less evidence of imagery than did subjects classified as inhibited; similar differences appeared for extroversion-introversion but were of borderline significance. In a further study with different subjects, Dunn and her coworkers found that subjects with high scores on economic, theoretical, and social values, classified together as objective, impersonal, and practical, gave responses more rapidly and with a higher proportion of contrast responses and with less imagery than did subjects with high scores on aesthetic, religious, and social values, classified together as subjective, personal, and impractical (to name the corresponding adjectives indicated above from among the many adjectives which differentiate the two groups). It would appear from these results that the manner of responding to a word-association test is related to the broad personality trait of impulsivity-inhibition and to broad values. Havron, Nordlie, and Cofer (1957) have also reported that subjects with religious or with political-economic values can be differentiated by their choices of which one of two words goes best with a stimulus word. In addition, the stronger the value the more rapidly the subject finished the test.

Moran (Moran, Meffered, & Kimble, 1964; Moran, 1966) has identified "idiodynamic sets" in word associations in both normal and schizophrenic subjects. Three of the sets, of which individuals characteristically give responses descriptive of one, are (1) object-reference, that is, responses which name another object often found in daily life with the stimulus object (for example, *Foot-shoe*); (2) concept-reference, that is, responses which are often synonyms (for example, *Small-little*), or superordinates (for example, *Cabbage-vegetable*) of the stimulus; and (3) rapid contrast and coordinate set, illustrated by *Black-white* and *Apple-orange*, which may exemplify a set for speed in response (Moran et al., 1964). These sets were found again in a later study (Moran, 1966), and a fourth set was also uncovered, which involves adjective-noun, noun-adjective associates and is called "perceptual-referent"; it enters into contrast with the rapid contrast and coordinate set. Although the evidence for these response sets appears to be substantial, Moran has apparently not yet studied their relationships to personality measures or behavior in other situations.

As a final topic within this section, we may consider how well group norms represent the associative hierarchy of an individual subject. Considering the evidence we have summarized with respect to age, sex, occupation, nationality, and personality, it would be surprising if group norms were found to give an accurate prediction of individual response hierarches. We have already seen, however, that Rosen and Russell (1957) presented limited evidence for the comparability of individual and group hierarchies. Further evidence has been provided by Jenkins and his associates (unpublished data, cited by Jung, 1966, p. 129); Brody, (1964); and Silverstein, (1967). In the Jenkins study, subjects were asked to give associations to 50 stimuli on 8 consecutive trials. The comparisons of group and individual data, according to Jung, "demonstrated the equivalence of the two measures." Brody (1964) employed 30 stimulus words taken from Laffal's (1955) list and

obtained word associations to them on 15 consecutive trials. He obtained a correlation of .82 between the frequency with which a response occurred as an associate on the first presentation of the list (this is a measure between subjects) and the frequency of repetition of that response through the remaining administrations of the list. Thus, the repetition of an associate on subsequent tests is a positive function of its initial or normative frequency. Brody also showed that, where a subject did not repeat his first associate, he tended to give the normative primary, as established on the first test, even though he himself did not give that response on his own first test. This, too, shows the use by the individual of common word associates. Finally, Silverstein used two 20-item lists, each of which was presented three times in succession. The probability of repeating a response on trials 2 and 3 increased directly with the normative frequency of the response given on trial 1, and the inverse relationship was found for failures to repeat the trial 1 response on either of the subsequent trials. This again suggests a correspondence between the group or cultural hierarchy of responses for a stimulus and the relative strength of these responses for an individual.

In attempting to measure the response hierarchy for an individual, an alternative to the repetition of the test may be used, as in the studies just mentioned. The responses may be treated as varying in strength according to their order of occurrence, with the first response being the strongest. Garskof (1965) has computed correlations between the frequency of responses obtained in single-response free association and scores obtained in continued association. The score was based on the average rank in order of emission over 20 subjects, weighted by the frequency of occurrence among these subjects; the single response data were taken from 100 different subjects. The correlations ranged from .52 to .94, with 15 of them being over .70. This suggests that the order-frequency measure, based on a small group of subjects and continued association, yields results comparable to those obtained using a large number of subjects and the single-response method (see Cofer, 1958, discussed above).

Classification of Associations and Relational Measures. From the time of Galton to Laffal (1965) attempts have been made to classify the associations found for word-association stimuli on a basis other than frequency or other than parts of speech. Wells (1927), for example, suggested dividing associations into 5 types with respect to their stimulus words: (1) egocentric or subjective, which involves an emotional or personal reaction to the stimulus word (for example, *Success-I must*); (2) supraordinate (for example, *Table-furniture*); (3) contrast (for example, *Black-white*); (4) miscellaneous, which is a large class; and (5) speech habit (for example, *Forward-march, Black-board, Deep-depth*). Woodworth (1938, p. 352) suggested a 4-way classification: (1) definitions, including synonyms and supraordinates; (2) completion or predication; (3) coordinates, including contrasts; and (4) valuations and personal associations. Examples of these classes, taken from the associations to the stimulus *Needle,* are (1) *instrument, tool;* (2) *sharp, eye, work;* (3) *thread, thimble, cotton;* (4) *hurt, sting, blood.* Laffal's (1965) method of analysis provides many categories into which the relation between a response and its stimulus may be classified (see page 885). The earlier classification systems have been summarized by Woodworth (1938, pp. 348-354), Woodworth and Schlosberg (1954, pp. 52-56); Osgood (1953, pp. 708-712); and Deese (1965, pp. 21-29).

Such classifications as those described above imply bases for organization or for the structure of associations. This is to say, for example, that if a large proportion of all word associations can be classified as definitions or coordinates of stimulus words, whatever psychological processes lie behind definition or coordination would be the foundation for the way associations are organized and for the occurrence of these kinds of responses in

association tests. Further, if people differ in which kind of association is dominant (and this is suggested in Moran's work, mentioned above), then association test behavior may represent different associative, or, even, "mental," organizations the implications of which could be sought in other situations and tasks. Unfortunately, relatively little has been accomplished along these lines. Most of the classifications proposed have been based on logical analyses of the relations between stimuli and their responses but have gone little further. Except for an occasional program, such as Moran's, little has been done to identify individual differences systematically in terms of the classification of associations or to relate such individual differences to other behaviors.

So far as the structure of associations is concerned, the work of Deese (1965) and of Laffal (1965) represents a departure from the classification systems of the past, for they analyze associations in terms of measured overlap in the response distributions obtained for two or more word-association stimuli. Because their work is predicated on relational measures, it is taken up in the next section, after these measures are described.

Measures of Associative Relations. If a stimulus word elicits another word as a response, we can say that they are associatively related. Thus (see Table 19.2), *Sacred* and *Holy* are related because *Sacred* was found to elicit *holy* 57 times from a group of 350 subjects, and *Holy* to elicit *sacred* 53 times. The simplest way of describing an associative relation,

TABLE 19.3 INTERITEM ASSOCIATIVE MATRIX FOR FIFTEEN HIGH-FREQUENCY ASSOCIATES OF BUTTERFLY[a]

	Moth	Insect	Wing	Bird	Fly	Yellow	Net	Pretty	Flowers	Bug	Cocoon	Color	Stomach	Blue	Bees	Average
Moth		2	2		10				2	10						
Insect	4				18					48					2	
Wing				50	24											
Bird			6		30									2		
Fly		10		8						18						
Yellow									3			11		16		
Net	2	2		2

Blue												10				
Bees				15					5							
	24	56	8	81	86	2	0	0	10	86	0	23	0	40	8	28.3

[a] The numbers presented in the table are percentages. Reprinted with permission from Deese (1961, p. 18, Table 2.1).

then, is to indicate the proportion of times one word occurs as an associate to the other. In the case of *Sacred* and *Holy,* however, there is the additional fact that each word, as stimulus, elicits the other as response, and at about the same frequency. The association for these two stimuli, then, is bidirectional. There are cases of unidirectional association, of course, in which a stimulus, such as *Little,* elicits a response, such as *man,* at some frequency, but the reverse association, *little* as a response to *Man,* does not occur (Palermo & Jenkins, 1964). Also there can be bidirectional associates in which the frequencies are not equal. For example, *Little* elicits *boy* from 8 percent of the subjects (Table 19.2), whereas *Boy* elicits *little* in less than 1 percent of college subjects (Palermo & Jenkins, 1964). In order to assess the nature of the associative relation between two words, it is desirable to have available the associative distributions for both of them as stimuli. Otherwise the bidirectional or unidirectional character of the relation is unknown, as well as the relative strengths of the two associations.

The associative relations among more than two words is also of interest, and several measures have been described (see Marshall and Cofer, 1963). One is the *Index of Inter-item Associative Strength* (IIAS), described by Deese (1959a) in the context of studies of the recall for lists of words. Suppose we take 15 words, all of them associates to one word, say *Butterfly,* such as *moth, insect, bug, wing, bird, fly,* and so on. To obtain IIAS for the set, we must first obtain free associations to each of these associates. Having done so, we can then determine how often each of the associates occurs as a response in free association to each of the other associates when used as stimuli. An illustration is provided in Table 19.3 for the first 15 associates to *Butterfly.* The index for this set is 28.3, one of the highest of those used by Deese.

A simple index can also be used for controlled associations. For example, Cohen, Bousfield, and Whitmarsh (1957) asked subjects to give instances appropriate to a stimulus that was a category name. This involved controlled association because the subjects were not free to give just any response. Over a large number of subjects certain responses were found to occur with high frequencies, others with low. For the category "four-legged animal," for example, *dog* and *cat* occur at high frequencies, *zebra* and *giraffe* at intermediate frequencies, *aardvark* and *llama* at very low frequencies.

A somewhat different approach to this kind of associative measure has been taken by Rothkopf and Coke (1961a) and by Pollio (1963). For a set of stimulus words, Rothkopf and Coke's measure (the cue number) is the number of the stimuli which elicit a given response. They (1961b) have given the cue numbers for 99 of the Kent-Rosanoff stimuli.

Pollio (1963, 1964) has analyzed associative relations by means of matrix algebra. He sets up a matrix, to begin with, in which the words in the set are listed across the top and also down the left side. The cell entries are either "0" or "1," with the "1" meaning that a given word occurred as an associate to another word in the set (frequencies of occurrence are ignored). By multiplying out these matrices, Pollio has been able to describe various ways in which the items of the set are interrelated.

Measures of association like those described above, as already indicated, take account only of the occurrence of one stimulus word as a response to another stimulus word and conversely. As is indicated in Table 19.2 for *Sacred* and *Holy,* there are other words besides these that occur as common associative responses to both, for example, *church, God,* and the like. For convenience we may refer to the elicitation of one of two stimulus words in a set by another one in the set as *direct associates;* in this example, *sacred* and *holy,* as responses respectively to *Holy* and *Sacred,* would be direct associates; *church* and *God* would be *nondirect associates.* Measures have been developed that take account of both direct and nondirect associates. One such index is the *Mutual Related-*

TABLE 19.4 DATA FOR COMPUTATION OF ASSOCIATIVE OVERLAP (MR) FOR STIMULUS WORDS SACRED AND HOLY

Common response words	*Sacred* (A)	*Holy* (B)	*Common Frequencies* (R_c)
Sacred	(350)	53	53
Holy	57	(350)	57
Church	85	78	78
Cross	10	15	10
God	17	40	17
Religion	19	9	9
Religious	14	15	14
			238

$$\text{Overlap (MR)} = \frac{\Sigma R_c}{N_A + N_B} = \frac{238}{700} = .34 \quad \text{where } N_A = N_B = 350,$$

or

$$\frac{\Sigma R_c}{\sqrt{(N_A \cdot N_B)}} = \frac{238}{700} = .34 \quad \text{where } N_A = N_B = 700.$$

ness (MR) *Index,* developed by Jenkins and Cofer (1957) and by Bousfield, Whitmarsh, and Berkowitz (1960) (see Marshall & Cofer, 1963, pp. 410–413).

Table 19.4 shows the associative responses that are made to *Sacred* and *Holy* (thus several responses to each stimulus alone, listed in Table 19.2, are not present in Table 19.4). The index indicates the common responses for both words as a proportion of all the responses in the distributions for them. Thus, in column R_c for the response word *religion,* the value 9 appears; it is 9 rather than 19 because only 9 responses of *religion* are made in *both* response distributions. These 9 are common, whereas the other 10 responses of *religion* to *Sacred* are not common to the two distributions. In column R_c, the lower of the two values for a given response is entered (in the case of equal response frequencies, say 10 and 10, the value 10 would be entered as R_c). Summing the column R_c and dividing by the total N (350 subjects in each distribution, thus 700) gives an index for this pair of 0.34. Deese has used the same index, calling it an *Index of Commonality of Associative Meaning,* except that he divides R_c by the geometric mean of the number of cases in the distributions and makes the N of each distribution 700, thus taking account of the values in parentheses in Table 19.4. (See Deese, 1965, pp. 51–52.) His IC value for the two words of the table is the same as that shown in Table 19.4. The argument for taking the N for each word as twice the actual number of subjects (350) used is that before giving his association the subject repeats the stimulus word to himself. Thus, *sacred* and *holy* each occurs as a response when *Sacred* and *Holy,* respectively, are presented as stimuli, and this fact is acknowledged by putting 350 in parentheses in Table 19.4 for each. This assumption permits the counting of the 53 occurrences of *sacred* as a response to *Holy* in R_c, for *sacred* always occurs as an implicit response to the stimulus *Sacred* but only 53 times to *holy.* An index closely related to MR, called the *Index of Generalization,* has been proposed by Bousfield, Whitmarsh, and Danick (1958), and another one, *Associative Overlap,* by Rothkopf (1960).

Indices which, like IIAS, can be extended to more than two words, have been developed by Marshall and Cofer (1963). One is the *Index of Total Association,* which includes both direct and nondirect associations common to any two or more words in the set. Another, the *Index of Concept Cohesiveness,*

takes account *only* of response words common to *all* the words of a set. An index related to both of these indices is the *Measure of Stimulus Equivalence,* proposed by Bousfield, Steward, and Cowan (1961). All of these indices are based on the assumption that common associations, other than direct associations, should be used to measure the associative relatedness of words. Because they have been fully described elsewhere (Marshall & Cofer, 1963) but have not yet had extensive use in experimental work, they are not treated further here.

It is worth mentioning that Underwood and Richardson (1956) have described a measure which they have used to calibrate verbal materials for use in the study of concept attainment. First, they obtained controlled associations to words like *Brick, Cherry, Tomato,* and *Lips.* Their subjects were restricted by instruction to give only "sensory" associations to each word, for example, *red.* To the word *Cigar,* 40 percent of the subjects gave *smelly,* 26 percent gave *brown,* and 14 percent gave *long* as sensory responses. *Smelly,* in this case, is the dominant response, and the others are less-dominant responses. In using materials like these to study how concepts are formed, we would choose, say, four words, like *brick, cherry, tomato,* and *lips* and ask our subject to indicate how they are alike or what they have in common. The dominance level of the correct sensory impression can be varied for the sets of words employed, and when this is done success on the problem is found to be related to the average dominance of the correct response as a controlled associate to the members of the set.

Garskof and Houston (1963) have developed a measure, the *relatedness coefficient,* or RC, which can be used for individuals to determine the associative relatedness of words. Their procedure involves, first, obtaining continued associations for each stimulus word and ranking the responses in order of occurrence. Then the ranks of the words common to the two stimuli are multiplied and divided by a denominator that represents the maximum possible overlap. For example, suppose that the common responses to the stimuli *Eagle* and *Bird* are *bird, fly,* and *nest.* To *Eagle* these responses occur at ranks 5, 3, and 2 and to *Bird* at ranks 3, 4, and 2. Multiplying these ranks gives 15, 12, and 4, and assuming five response words for each, multiplying them ($5 \times 5, 4 \times 4, 3 \times 3, 2 \times 2, 1 \times 1 = 55$) gives 55. Adding the ranks for the three common words yields 31, subtracting one from 55 gives 54, and dividing 31 by 54 yields an RC for this case of .57. RC can vary from zero to 1.00. Garskof and Houston found this measure to be highly related to judgments of the relatedness of pairs of words, the rank-order correlations for 20 subjects, ranging from around .90 to about .60.

Garskof and Marshall (1965) computed RC and MR for 2 sets of word pairs. In one set, the pair members had direct associations in common but in the other set did not. For the first set of pairs MR and RC correlated (r) at .540 and for the other set at .504. These correlations indicate that the 2 measures are related, but not highly. However, the samples of pairs used were not large (34 and 20 words), and so the full extent of the relation between these measures is not known. Little has been done to compare the utility of various other indices mentioned in this section, but all of them differ to some extent from one another and would not, therefore, be expected to be very highly interrelated.

In the two sections that follow, measures of associative overlap figure importantly in considerations of the structure of associations and in studies of the relationship of preexisting association to performance in verbal learning situations.

The Structure of Associations. In the beginning of this chapter, we mentioned the laws of association. These laws, especially the primary ones, imply the bases on which associations are organized and identify the kinds of dimensions which underlie associations between words, that is, contiguity in experience, similarity, and contrast. As was said
Figure 19.4. First and second factor loadings for 15 religious-value words for (a) subjects scoring high and (b) for subjects scoring low in religious value. (From data presented by Deese, 1965, Table 12, p. 84.)

then, Deese (1965) has argued that the identification of the laws and the structure of associations on the basis of introspective evidence may be faulty. His point is that the temporal sequence of items in thought may not indicate how the items of thought themselves became associated. Thought and language have an intrinsic sequential character, and evidence from introspection, which is like thought and which involves language, may lead to erroneous ideas as to how the items became associated in the first place.

Deese has studied the associative interrelations of words in the following way. First, he has collected single-word free associations from each word in a set of words and has then calculated the index of associative commonality for every pair of words in the set. Following this, he has factor-analyzed the commonality coefficients in order to identify the basic dimensions that underlie the interword associations of the set. The results of these procedures have led him to postulate two new laws of association. The new laws are as follows: "(1) Elements are associatively related when they may be contrasted in some unique and unambiguous way"; and (2) "Elements are associatively related when they may be grouped because they can be described by two or more characteristics in common" (Deese, 1965, p. 165). The evidence which has led to these laws is our next concern. Comment on the laws will be made later.

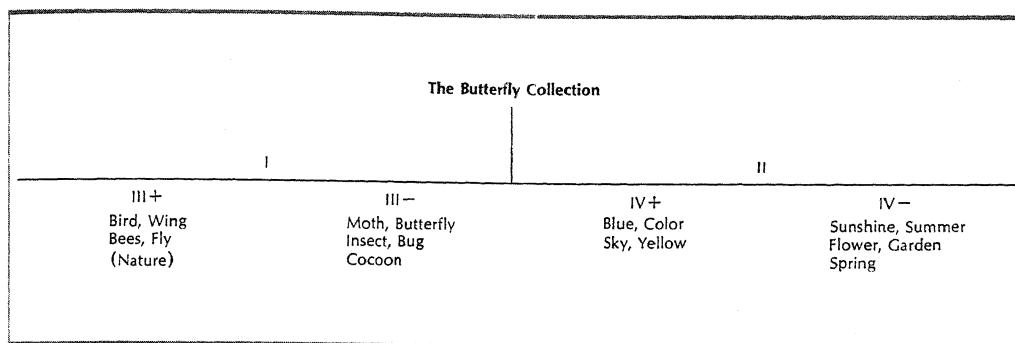
Among the sets of words Deese analyzed are 15 words having to do with religion. Associations were obtained for each of these words from a group of subjects for whom religion had a high value and from another group for which religion had a low value. In Figure 19.4 the first two factors for this group of words are plotted for both groups of subjects. It may be seen, for both kinds of subjects, that the words are cleanly divided by the two factors, though the composition of the factors is slightly different for the two kinds of subjects. For the highly religious students, *religion, worship, reverence, prayer, spirit, divine, faith,* and *devotion* are found


Figure 19.5. Tree diagram for the words in the *Butterfly* collection based on their loadings on the first 4 factors extracted. (Cofer, 1967, Fig. 9, p. 10, from data reported by Deese, 1965, Table 7, p. 76, and Fig. 2, p. 78.)

together on Factor I; *sermon, clergyman, service, soul, inspire, love,* and *hope* are found together on Factor II. Perhaps for them, Factor II words are related to church services, whereas Factor I words have more to do with the nature of their religious involvement. However this may be, it is clear that the factor structure clearly separates out words which go together from other words. For a set of 19 words which, to begin with, were the stimulus word *Butterfly* and its associates, Figure 19.5 displays in a tree diagram the items that appear on the first four factors extracted from the matrix. Again, there are clear separations, the first two factors splitting the words into animate and inanimate sets. Factor III splits the animate words into two groupings, and Factor IV does the same for the inanimate words. Factors III and IV imply contrasts between the sets of words on each factor, for these factors are bipolar. Deese has reported that his analyses of associations yield similar findings for various other word sets. This is true for 17 words related to *Music,* 16 related to *Slow,* 50 aggressive words, 14 verbal auxiliaries, 11 personal pronouns, and 7 conjunctions. Clearly, there appears to be an underlying order among the common associates for sets of words, and for the auxiliaries, pronouns, and conjunctions this order parallels grammatical function. How may this underlying order be characterized? The two laws of association, mentioned earlier, represent a summary of the characterization of this order. They were reached in the following way (adjectives and nouns will be our main concern). Deese suggests that the structure of verbs (aside from the auxiliaries) will resemble that for nouns. Adverbs yield mainly syntagmatic associations, and this characteristic suggests that their associates come largely from their immediate verbal environments (for example, mainly because . . . , blissfully happy . . . , and so on).

Study of associations to adjectives, as we saw earlier, revealed that high-frequency adjectives tend to elicit paradigmatic associates; infrequently occurring adjectives yield syntagmatic associates. Deese suggests (1965, p. 120) that the members of this latter group take their meaning, typically, from a root which is a noun; this fact, he thinks, would cause them to have syntagmatic associates.

A large proportion of the high-frequency adjectives appear to generate paradigmatic associations by eliciting contrasts as responses (for example, *Hot-cold, Slow-fast, Dark-light,* and so on). To test this proposition and to study it further, Deese obtained free associates to each one of 278 adjectives known from word counts to occur 50 or more times per million words in English. He then calculated by means of a computer the 38, 503 overlap coefficients this set of adjectives provides. He examined first 39 pairs of adjectives in which each member of the pair elicits

the other as its primary and subjected their overlap coefficients to factor analysis. The result was that the polar opposite for a given word was the only one that had a substantial loading on the factor for that word. Words from the other pairs were simply unrelated to any given pair by this method of analyzing their associations.

The suggestion, then, is that the contrast pairs define a large number, perhaps 40 or more, independent dimensions of associative meaning. What of other adjectives, not included in this set of contrasting adjectives? Part of the answer is suggested by the use of the word *dimension* just now: Many adjectives are related primarily to other adjectives, which themselves relate to those which form contrasts (and to each other). Thus, if a basic contrast is provided by *big* and *little*, we find that *tiny, slight, small, large, great, grand, vast, huge* are related to *big* and *little* (and to each other) and in a way that describes a scale from one end of the dimension to another. Deese estimates that around 64 percent of the adjectives he used are either found in contrasting pairs or in one or more scalar dimensions anchored by such pairs. Many of the remaining ones, he thinks, would fit into this scheme if more data were available. Other adjectives, which do not enter into this scheme, are the color adjectives. They do not form contrasting pairs and their associative overlap coefficients generate several factors, such as the one we saw for the butterfly collection (Figure 19.5); they, then, tend to resemble nouns in this regard (and they are, of course, color *names* as well as adjectives).

The contrast arrangement, Deese suggests, arises because the contrasting adjectives can occur in common linguistic contexts. Thus, we can say "the tiny bird," "the large bird," "the small bird," and so on, "the big boy," "the little boy," or "the fast train," "the slow train," and the like, given that the choice of the adjective is determined by the actual feature of the bird, boy, or train of which we are speaking. Such common contexts presumably provide a way in which the contrasting adjectives become associated. There are others, of course. For example, one training drill, used in many language arts classes in the grade school, emphasizes the relation of opposition and, in doing so, provides pairings of the common adjectives representing these contrasts.

For nouns (and presumably for verbs), however, a different kind of organization must exist. This statement is supported by the fact that contrasts are perhaps the exception rather than the rule among nouns. It is also true, as we have seen for the butterfly collection, that the associative structure of nouns is multidimensional. Deese suggests, in consequence of these facts, that another principle must underlie the associative structure of nouns.

This principle, as summarized in the second law of association, is that nouns are organized in terms of common features, that is, they are grouped together conceptually, rather than in terms of their common linguistic environments. In their pattern of common associations, one way in which their common properties is manifested is through their common adjectival associates; a given noun, Deese says, "selects" some adjectives and "rejects" others. Kittens and puppies can be grouped together, he points out, because they are warm, young, furry, helpless, cute, and the like. However, the dominant associations to nouns are other nouns, and this fact must provide the basis for the grouping of nouns into sets, along with commonality of adjectival descriptions. The noun associates are of two kinds: one is the same "type" as the stimulus—for example, *Academician* yields *scholar, student, professor,* and so on. The other "type" consists of nouns "that are merely present with or related to" (Deese, p. 144) the stimulus—for example, for *Academician* instances are *academy, study, school, university, diploma,* and so on. Perhaps the first type may be regarded as synonyms or quasisynonyms; the second type is composed, at least to some extent, of coordinates (the terms "synonym" and "coordinate" are not used by Deese). These 3 kinds of associations—attributive and nominals of the same

or different type—together with a fourth category, "Other"—are said by Deese to characterize the associates to nouns. The first 3 kinds, of course, are related. Nouns grouped together share attributes, and those of the same type share conceptual or physical environments with nouns of different type, as *academician, student,* and *professor* can share the environments *school, university,* or *academy.* The organization of the associations in the case of nouns is, then, conceptual.

There is a parallel between these views of association offered by Deese and those expressed by Laffal (1965). Laffal, as we said earlier, has classified associations according to a system of categories. Then he has computed overlap measures for stimuli in terms of the categories (and their frequencies of occurrence) of the associations the stimuli elicit. Subjecting these measures to factor analysis, he finds structures for sets of words that appear generally similar to those obtained by Deese, as exemplified by the Butterfly collection. These findings have led Laffal to say "that there is a basic category structure in vocabulary and that associations reflect this structure."

It remains to discuss a little further Deese's laws of association and his suggestions as to the conditions under which they operate to bring a word into an associative relation with other words. It is obvious that he has retained the principle of contrast, though in doing so he has highlighted common linguistic environments as the reason that contrasting adjectives become associated. It appears to the writer that Deese has retained the principle of similarity, in some sense. The group of conceptual relations among associated nouns (and verbs) seems to involve a common feature (or element), and this notion is certainly one way of describing similarity. His emphasis on the group of associatively related words as a *structure,* whatever that may mean, has not been prominent in classical association theory. However, it is in his rejection of contiguity of experience that Deese is the most rejecting of the association theory of the past. In learning new items, Deese goes on to say, "we assimilate them to existing groups or establish them with reference to some fundamental attributive contrast" (p. 165). Clearly, this suggests the influence of organizations that are already in existence, but new groups may appear "when there are a sufficient number of objects in experience and memory to establish some new and unique collection of attributes" (p. 166). The rule here is represented by concept formation rather than by associative learning as in the case of paired associates, and one may view associations "as generated from structural types or schemata" (p. 177), after, presumably, a structure has been formed.

Unfortunately, little is known about the conditions under which the associations revealed in association tests are established. Implicit in Deese's discussion of the different "types" of noun associates (the ones referred to by the writer as perhaps being coordinates) is, in the writer's view, the principle of contiguity—spatial, in all likelihood, rather than in the form of temporal succession. Most of us have seen academicians in universities or read that it is in universities that they will be found. It seems too early to the present writer to abandon the principle of contiguity, but the impressive evidence Deese and Laffal have accumulated for the existence of associative structures certainly sets an explanatory problem for the doctrine of association by contiguity.

Relational measures and verbal learning

With relational measures, the greatest amount of work has centered on the Paired Associates and the Free Recall situations, and information with regard to the measures and the serial learning and verbal discrimination tasks is sparse. However, in the discussion that follows, we cannot review the entire literature concerning relational measures and any verbal learning situation and will, therefore, concentrate on studies illustrating major problems.

Serial Learning. Using the serial anticipation procedure, Underwood and Postman (1960) found no differences between a list of

12 high-frequency 3-letter words and one composed of low-frequency 3-letter words in either trials to achieve criterion or in mean errors per trial. If high-frequency words are interassociated to a greater extent than low-frequency words, as there is reason from Deese's (1960) work to expect, we might have expected the high-frequency list to be more difficult to learn than the low-frequency list because the inter-word associations for the high frequency words should have interfered with the learning of the items in the sequence required in the experiment. There was, however, a somewhat larger proportion of intra-list errors for the high-frequency list than for the low-frequency list, in keeping with this expectation. Postman (1961), however, did find more rapid learning of a serial list composed of high-frequency 2-syllable adjectives than of a comparable low-frequency list. Again, however, intra-list errors, presumably reflecting associations between items, differentiated the two lists. Errors made in response to high-frequency words came at positions more remote from the correct item than was the case for low-frequency words. The more rapid learning of the high-frequency list in this case seems to be due to greater item availability, which apparently overcame the *intra-list intrusions* generated by associations between items.

If a serial list were composed such that the items followed one another in congruence with their associative relations, we might expect faster learning for such a list than for one in which the succession of items bears only a chance relation to associative interrelatedness, as was the case with the lists in the experiments just mentioned. Weingartner (1963) ran an experiment in which the arrangement of the serial items was organized to reflect the factor structure found for associations by Deese (see above). He used 16-item lists. In one arrangement (*moth, butterfly, insect, bug, bird, wing, bees, fly, blue, color, sky, yellow, sunshine, summer, garden, spring*), the words were presented in an order which preserved the factor structure shown in Figure 19.5, Factors III and IV. In other orders, this arrangement was disrupted, including one in which the sequence of the 16 words was random. For the first, most orderly arrangement of the items 9.0 trials were required to learn the list, whereas for the random order (which remained constant over presentations) the mean was 15.2 trials. Clearly, the preservation of the associative relations between items in the first list gave it a marked advantage over the list in which the same items were used but in which their associative structures were disrupted. It is probable that these findings illustrate positive transfer from prior associations between words in the case of the first arrangement and negative transfer in the case of the disrupted arrangement.

Verbal Discrimination Learning. Underwood (1965) has reported that errors can arise in a recognition situation if a given item in the test has a strong associate (see also Schwartz & Rouse, 1961; Cramer, 1965). In his study a list of 200 words was recorded and then presented, one at a time at a 10-sec rate. As he heard each word, each subject judged whether or not the word had been presented earlier in the list. To illustrate what Underwood did and found, let us suppose that *dark* and *heavy* appeared fairly early in the sequence of 200 words and in different ordinal positions. Later on in the list (at least 30 serial positions later) the word *light* appears. Now *light* is an associate of both *Dark* and *Heavy;* if at the time the subject heard these latter two words he made the implicit associative response (IAR) *light* to either or both of them, we might expect that, when *light* is actually presented later on, the subject will judge it as having been presented before. In fact, this happened. In a group of 107 subjects, *light* was judged as having occurred before by 42 subjects, as compared to 13 times for a suitable control word. Underwood describes several other conditions which, apparently capable of arousing an IAR at the time one word is presented, produce false recognitions of this kind.

In verbal discrimination learning, one of

the members of a pair is arbitrarily designated by the experimenter as correct. What happens if the pair members are interassociated? Ullrich (1966) has reported that the more highly associated two words are, the more difficult it is for the subjects to learn to discriminate them in the verbal discrimination task. This is perhaps because, when the subject is told that one pair member is correct, he cannot, in view of the IAR which produces the other one, remember which one was said to be correct. Eckstrand, Wallace, and Underwood (1966) have provided evidence of a somewhat different kind. In one list, for example, two words that are associated were placed in different pairs. In one kind of pair the associated words were both correct (for example, *Queen* (+)– *fast, King* (+)– *pepper*); in another list one word was correct, the other incorrect (for example, *Queen* (+)– *fast, King-pepper* (+); in still a third list, both associates were wrong in their respective pairs. As compared with a control, fewer errors were made on the pairs where both associates were correct; the items in which the associate was right in one but wrong in the other pair produced the largest number of errors, and there was little difference in errors between the control condition and the case in which the associates were wrong in both pairs. These findings indicate the role of IARs in verbal discrimination learning, although a more complete account of the findings just summarized requires consideration of frequency factors, as is indicated in a later section.

Free Recall. Deese (1959a) set up lists of 15 words each in such a way that the lists varied in the inter-item associative strength (IIAS) over a wide range. He obtained free recalls after a single presentation of each list. The correlation (r) between the number of items recalled and the IIAS was 0.88 (see Cofer, 1967, for a successful replication). Deese also reported that *intra-list intrusions* were less frequent for the lists high in IIAS than for those low in IIAS and that the intrusions given in the recall of a list high in IIAS were "agreed" upon by subjects, whereas the intrusions were scattered over many subjects in the lists with low IIAS (see Deese, 1959b). There have been several other reports in which measures of association have been found to be related to the amount of free recall (Bousfield et al., 1960; Rothkopf & Coke, 1961a). Marshall (1963) found modest degrees of correspondence between MR (mutual relatedness; see p. 880) and the number of items in free recall.

In free recall we can study not only the sheer number of items produced but also the sequence in which they occur in a subject's recall. Remembering that in this method each subject is free to order the items in his recall in any way he chooses, we might anticipate that the order the subject adopted will reflect interrelations among the words of the list presented to him. One way in which these interrelations could be manifested in recall is that related words might be placed together in sequences, that is, in recall *clusters* of related words might be produced. One reason for the great interest in free recall over the period since about 1950 is that subjects do cluster related responses in their recalls and that the clusters bear regular relationships to independently determined relationships between words.

Jenkins, Mink, and Russell (1958) set up four lists of 24 words each. In one list the words were taken from highly associated pairs (for example, *man-woman*), and the degree of association between pair members was varied in the other lists, so that it was low in the fourth list (for example, *whistle-stop*). The 24 items were presented one by one; that is, the pair members were separated at the time of the single presentation. Jenkins and his coworkers were interested in whether the pair members would occur together in recall and whether the extent to which this associative clustering occurs would be related to the free association strength known from the norms to vary in the four lists. Both phenomena occurred, that is, associative clustering was observed, and its extent was directly related to the free association strength for the pairs. Thus, an average of 3.57 associative clusters

was obtained for the highly associated list and only 0.78 for the list with the least association. A number of other studies have confirmed these findings with several indices of associative strength (see Marshall & Cofer, 1963, for a summary and references).

Amount of recall and clustering are thus related to relational measures of association. We see a little later that there is another kind of clustering (category) and will be concerned with the question of whether it can be differentiated from associative clustering.

Paired-associate Learning. Because in paired-associate learning we ask a subject to learn a given response in conjunction with a particular stimulus, it would appear to be reasonable that learning rate should vary with the frequency with which that response is made to the stimulus in free association.

With adults, however, this expectation has not often been fulfilled. Several investigations (summarized by Jenkins, 1963, p. 215) have failed to obtain differences among pairs in which the free-association strength of the response to its stimulus varied over a range from 70 to 0.2 percent, although pairs with associative strength in this range are learned more quickly than unrelated (control) pairs. The associated pairs are learned very rapidly, so rapidly that measures such as trials to criterion and number of correct responses or of errors are perhaps insensitive to differences occasioned by variations in pre-experimental associative strength. Using latency of response as a measure, Shapiro (1966) found differences of the expected kind.

There are reports, however, in which the speed of learning is found to be associated with free-association strength under certain conditions. For example, Postman (1962; also Martin, 1964) found this relation to hold when the stimuli used were low-frequency words but did not find it when the stimuli were high-frequency words. This may suggest that properties of the associative hierarchy, as well as free-association response strength per se, are significant to the relationship obtained, a factor which Howe (1967, personal communication) has investigated, and which was summarized above when we considered interpretations of the relation of verbal learning to *m*, *m′*, and *av*.

With children, in contrast, relations between free-association strength and paired-associate learning have been obtained, and certain representative studies will be described. Palermo and Jenkins (1964b) used children's association norms (Palermo & Jenkins, 1964a) to establish pairs with high-strength primaries (32 to 44 percent) and with weak primaries (9 to 12 percent). Control pairs contained the same stimuli but unassociated responses. Mixed lists were used with fifth-grade children. Associated pairs at both levels were learned more rapidly than control pairs, and the ease of learning varied directly with the associative strength in the pairs containing stimuli and their primaries. Similar results have been obtained by several investigators at this grade level as well as at higher and lower grades.

The suggestion in these differences between children and adults in the relation of free-association strength to paired-associate learning is that perhaps for adults all the possible associative responses, whatever their strength, are so highly available to their stimuli that little effort is required to "learn" them in the paired-associate situation. With children, however, due to their having had less experience with the language, response availability varies in accordance with associative strength and is therefore reflected in PA learning.

A further finding in the study by Palermo and Jenkins (1964b) appeared with the control pairs. In these pairs, of course, the responses were unassociated with their stimuli. Yet control pairs in which the stimuli were known to have high-strength primaries produced fewer errors than pairs in which the stimuli were known to have low-strength primaries. What this finding appears to mean is that, if stimuli with low-strength primaries are used, there are more responses of moderate strength that can interfere with the learn-

ing of the unassociated response term than there are in the case of the stimuli with high-strength primaries. This is to say that the steepness or the shape of the hierarchy, as well as the absolute strengths of the associations themselves, are involved in the results of experiments relating free-association strength to rapidity of PA learning. This is consistent with the interpretation offered by Howe and mentioned above.

Several studies have also investigated PA learning in pairs in which the S-R associative strength varies as indicated by controlled association norms. As we mentioned above, Underwood and Richardson (1965a) used nouns to which they asked their subjects to give "sensory associations," that is, words descriptive of properties of the nouns that can be perceived directly via the senses. As we said above, response words vary in dominance level under these conditions. The question, then, may be asked: Will the learning of pairs vary as a function of their dominance levels? The answer is affirmative. Underwood and Richardson (1956b) found that if four noun stimuli were paired with a single sensory association, the mean dominance level for that association (for its four stimuli) was directly related to ease of learning. Parallel findings were reported by Underwood and Schulz (1960) for mixed and unmixed lists of pairs varying in dominance level.

Coleman (1963) required his subjects to give continued associations to stimuli, restricting the associations to adjectives. He argued that the first response obtained in this way should be stronger for a given subject than later responses. If, for example, the associates to *Doughnut* are *sweet, round,* and *crusty,* in that order, we should expect the sentence, *Doughnut is sweet,* to be learned more rapidly than the sentence, *Doughnut is crusty.* This would be so because there are no stronger adjective associations than *sweet* to interfere with the learning of the first sentence, whereas both *sweet* and *round* can interfere with the learning of the sentence, *Doughnut is crusty.* Using as learning materials sentences like those just indicated, Coleman obtained results confirming his expectations (see also Coleman, 1964).

Finally, there are also some preexisting "serial structures" that one brings to any learning situation that certainly influence both the ease of learning paired-associate (and other) tasks and the nature of the errors which occur. For example, almost all of us are aware of a dimension running from freshman to senior, with intermediate points (sophomore, junior) having determinate serial positions. DeSoto and Bosley (1962) used these terms as the responses in a paired-associate learning task, with the names of fictitious persons as the stimuli. The entire list contained 16 pairs to be learned, with 4 names associated with each of the responses. Thus, a subject had to learn to say "Junior" when he saw "Fred Brown," and "Freshman" when he saw "Harry Smith." The important point here is that the errors that occurred during this learning were "good" ones far more frequently than might be expected on the basis of chance: If a name should have been called "Freshman," the most frequent error was to call it "Sophomore," and the least frequent error was to say "Senior." Furthermore, the correct application of the labels "Freshman" and "Senior" was made most quickly, suggesting that subjects were using some type of end anchoring system, even though this had no real relevance in this situation. Pollio (1966) and Pollio and Draper (1966) have shown how such serial structures influence word associations and serial learning. Clearly, this is a property of verbal materials that is dependent upon our familiarity with a language and one which can have important influences on verbal learning.

Summary. From this rather brief and selective review of the evidence concerning relational measures and verbal learning situations, it is clear that relations between prior associations and learning are often substantial ones. It is also clear, however, that associative strength is not the only variable, for the presence of other conflicting associations must

also be considered in anticipating the outcomes of experiments of these kinds.

So far as paired-associate learning is concerned, there are many other studies in which free association has been investigated. These studies have been concerned with mediated transfer and therefore are outside the scope of the present chapter.

Conceptual relations Words may, of course, be related to one another in many ways aside from those encompassed in measures of associative relation. Actually, measured associative relations are often confounded with other ways in which words are related, and conversely. Words may bear many logical relations to one another—they may be synonyms, antonyms, coordinates, subordinate members of a class, class names for subordinates, members of the same form class, and so on. Dimensions of this kind, especially those of synonymity and antonymity, have sometimes been used in experiments on verbal learning and retention when the similarity between items has been a problem of interest to investigators. One question that can be raised at once is whether these properties are independent of one another and of associative interrelations.

This is not an easy question to answer, aside from the problem of the extent of the intercorrelations. This is to say, given a correlation, it is difficult to determine whether the associative relation is fundamental to the conceptual relation, or conversely. At the present stage of inquiry, we must be content with a statement of such correlative relations as have been established.

Haagen (1949)[8] selected 80 "standard" words, and for each standard word used five other words that appeared to have some degree of synonymity to the standard. He then asked subjects to rate each of the five words against the standard on a scale of synonymity. (A rating of 1 indicated high synonymity.) As an example, consider the following set of words: *Royal* is the standard word, and the five synonyms, with the rating of the degree of synonymity to royal, are as follows: *regal* (1.1), *kingly* (1.6), *stately* (2.4), *sceptered* (3.3), *ruling* (3.9). Cofer (1957) obtained free associations to a number of Haagen's words and computed associative overlap between a number of the words and their standard words. Figure 19.6 shows a plot of associative overlap scores against rated synonymity. Clearly, the words rated as highly synonymous also show high associative overlap, and the decline in rated synonymity roughly parallels the decline in associative overlap. For these items, then, synonymity and associative overlap vary together. If we wished to uncover the role of synonymity in some verbal problem, we would be well advised to control for degree of associative overlap.

Figure 19.6. Associative overlap in pairs of words as a function of judged synonymity between the members of the pair. (Synonymity ranges from high—0.9-1.3—to low—4.9+.) The numbers in parentheses along the abscissa indicate the number of pairs represented in the mean overlap score for the synonymity interval. (Cofer, 1965, Fig. 1, p. 262.)

The only other data known to the author that provide for an analysis of conceptual relations among words in conjunction with

[8]Similarity ratings for pairs of 2-syllable adjectives have been published by Hilgard (1951, Table 11, pp. 548-552). The data came from an unpublished study by Melton and Safier.

association were reported by Cohen, Bousfield, and Whitmarsh (1957). They selected a number of conceptual categories and asked subjects to provide instances of each category. The data, then, were obtained under instructions for controlled association. It is clear from their norms that certain responses are much more likely than others to be given as instances for a given category. For example, the category four-legged animals yields the words *dog, cat,* and *lion* at high frequencies, the words *zebra* and *giraffe* at much lower frequencies.

Only a few attempts have been made to study conceptual relations in conjunction with verbal learning situations, and even fewer have been controlled for associative overlap to allow for an assessment of the independent contribution of the conceptual factor. The writer knows of no studies of conceptual relations in regard to verbal discrimination learning, and such studies as there are of synonymity in serial learning are treated in the next section. This leaves free recall and paired-associate learning, to which we turn now.

Free Recall. Bousfield's (1953) first study of clustering under free recall conditions made use of a list of 60 words, 15 in each of the following four categories: vegetables, animals, professions, and men's first names. The items were presented in a randomized order, and the single recalls were scored for the occurrence of category clustering, that is, the appearance in sequence of items from the same category. Thus, using letters to indicate items from the categories just indicated, the following sequence would show four clusters: AVVVPAAVNPPNNNN. The clusters vary in size, from two to four items. Bousfield developed procedures for comparing the amount of clustering obtained with the amount expected by chance. He has found category clustering over a wide range of materials and has investigated extensively variables which are pertinent to it.

Because of his interest in clustering, Bousfield did not include a control list of unrelated words, but Underwood (1964, pp. 63-65) has reported that word lists that contain categorized items produce more items in recall than comparable lists of unrelated words. Cofer (1967a) obtained similar findings. However, the interpretation of the augmentation of recall is not entirely clear, that is, it is not certain whether it is the categories or perhaps associative interrelations among the items in the categories that are responsible for the augmented recalls of lists of categorized items. It is also possible that the increased recall, on either basis, may represent not so much an increase in the number of items remembered but rather the fact that category and associational relations may permit a subject to generate additional items on the basis of those he does remember. A generative process, accompanied by the ability to recognize which of the items generated were and were not on the list presented, would account for the augmented recall. Cofer (1967a) has summarized evidence for this generative and editing interpretation.

However, categorization has been found to be related to the amount of clustering and to some extent to the number of items produced in recall, when the degree of associative overlap is equated. Marshall (1963) studied lists composed either of pairs or of four-word sets of words (presented in a randomized order). The pair members were either readily categorizable (for example, *Eagle-Crow*) or were not easily categorized (*Soft-Silk*). Marshall arranged to have pairs of both types (and four-word sets) in which associative overlap was equated. As indicated, he found that categorized members clustered more and were somewhat better recalled than noncategorized items, although these differences appeared mainly at low and intermediate mutual relatedness (MR) levels. Where associative overlap was high, it made no difference whether the pair members were categorized or not.

In a study of some of Marshall's pairs, Cofer (1966) asked subjects to write a word or phrase which could link or relate the

members of the pair. He tabulated the number of such words or phrases for the two kinds of pairs, finding that about half as many such words or phrases were given for categorized pair members as for uncategorized pair members. This means that there is better agreement on which linking words or phrases are to be assigned to the categorized than to the noncategorized pairs. This suggests that categorization may provide a ready means of coding categorized pair members. Whether this should be interpreted as an associative mechanism of coding is perhaps impossible to say. Incidentally, there was no relation between the number of linking words or phrases and MR level, for either kind of pair.

At the present time, it is not possible to reach a firm conclusion with respect to the role of conceptual relations in free recall, in view of the question of confounding with association. (For a contrasting viewpoint, see Mandler, 1967.)

Paired-associate Learning. The situation is little better in the case of paired-associate learning. In the author's laboratory, evidence for more rapid acquisition over the first five trials of PA learning of categorized than of uncategorized pairs has been obtained (after being equated for associative overlap). It is uncertain how far this finding can be generalized.

Richardson (1958, 1960) has used a kind of paired-associate learning, in which he paired several stimuli with the same response. The stimuli with a common response were similar (for example, *sacred, divine, hallowed, holy*), were members of the same class (for example, *pine, maple, walnut, elm*), had a common property (*barrel, doughnut, knob, balloon,* all of which are round), or were unrelated (*perfect, dirty, removed, rising*). Several sets of stimuli were used in each list. Some advantage was present in paired-associate learning for the lists containing sets of similar stimuli and for sets of stimuli belonging to the same class; it is possible, of course, that these sets of stimuli were associatively interrelated (see also Cohen & Hut, 1963). Hence, it is uncertain at the present time how much credit should be given to the conceptual relations involved and how much to inter-item associations.

Inter-item similarity Similarity between items in a list can take several forms. These same forms of similarity, of course, can be present between lists, and this similarity has been of interest to investigators working with transfer between lists and interference effects. In this chapter, however, we confine our discussion to the similarity between items (or within lists) so far as acquisition is concerned.

Variations in similarity can be accomplished in several ways. With nonsense-syllable and CCC trigrams, similarity is usually defined in terms of letter duplication. Thus, *GAX* and *DUP* have no letter duplication, whereas *DUP* and *DAX* have 1, and *DUP* and *DUX* have 2 letter duplications. In the case of words, high associative overlap between words would indicate associative similarity, as would conceptual relations, such as synonymity and common class membership. We have, of course, already described several of these ways in which words may be similar.

Similarity has a profound effect in the acquisition phase of verbal learning. It is now common (Underwood & Schulz, 1960a, pp. 92–94), however, to divide acquisition itself into two processes or stages (on which inter-item similarity may have different effects). One stage is response learning or response integration. During this stage, the subject learns what the responses are and, in the case in which the responses represent unusual combinations of letters (for example, TPL), he must also learn the combination as a unit. The second stage is the associative or hook-up stage, in which the responses become associated with their stimuli.

The response learning stage is usually regarded as being reflected especially well in free recall. This is because the responses in free recall are not associated with specific stimuli. We have seen that various kinds of

similarity between words appear to augment free recall, and we see below that, in general, similarity between items is thought to facilitate free recall. In discriminating items, as in a recognition test, for example (see Bahrick & Bahrick, 1964; Bruce & Cofer, 1967), subjects have difficulties when the items are similar. In the associative stage in serial learning and in paired-associate learning, inter-item similarity is also a factor which makes learning difficult.

An illustration of the different effects of the similarity between items on free recall and on the formation of associations is provided by an experiment reported by Underwood, Runquist, and Schulz (1959). They began with five presentations of two different lists of words, obtaining a free recall after each presentation. One list contained 10 nearly synonymous words (for example, *sunny, carefree, cheerful*), the other 10 unrelated words (for example, *rounded, spicy, hairy*). The number of correct responses over the first three trials of this procedure was greater for the list with similar items than it was for the list of unrelated words. These two lists were also employed in paired-associate learning (with nonsense syllables as stimuli). At certain trials, free recall of the response terms were obtained. In the early trials, free recall was again greater for the similar than for the unrelated items, but, over 15 trials of paired-associate learning the reverse took place, that is, more correct responses were given for the list of unrelated words than for the list of similar words. If the free recall procedure indexes the response learning stage and paired-associate learning the associative stage, we can say that similarity between items facilitates the former and retards the latter stage of learning.

Somewhat similar results were reported by Horowitz (1961) for serial learning of 12 trigrams. One list of trigrams was made up from only four letters (high similarity), the other from 12 different letters (low similarity). Each list was learned by a free recall group and a group which had only to reconstruct the serial order of the trigrams, the trigrams themselves being provided on a set of 12 cards. More similar than dissimilar trigrams were recalled over the first five of 10 trials of the free recall procedure, whereas the dissimilar trigrams resulted in a higher score than the similar trigrams on a measure of success in reconstructing the serial order over the 10 trials. If serial ordering requires learning in the associative stage, the results again show more rapid learning in this stage for dissimilar items, whereas free recall showed better learning for the similar items. Whether this conclusion for trigrams can be generalized, however, beyond Horowitz's particular high-similarity list is doubtful (see Underwood, Eckstrand, & Keppel, 1964, pp. 207–208).

Aside from the influence of similarity between items in relation to the two stages of learning, there is other evidence that it may have profound effects. In paired-associate learning, Underwood and his coworkers (1964) used color names as stimuli and trigrams as responses. In one list, the six trigrams were dissimilar, no letters being duplicated, but the trigrams in the other list were similar, being composed from only five letters. In 15 trials the dissimilar list yielded a mean of 31.50 correct responses per subject, whereas the similar list yielded only 5.77 correct responses. This difference, five- or sixfold, illustrates the profound effect interresponse similarity can have in the PA situation.

In another experiment with this task, Feldman and Underwood (1957) used lists of seven pairs. In one case, the stimuli were similar trigrams and the responses unrelated words. This list required 28.53 trials to learn, whereas with the same responses but with dissimilar trigram stimuli only 15.13 trials were required. Combined similarity between stimuli (trigrams) and between responses (words), in another condition, yielded a list requiring 34.20 trials to learn.

As can be readily guessed, similarity is a factor in serial anticipation learning. Using a list of 14 similar adjectives, Underwood and Goad (1951, Table 1, p. 127) reported that this

list required 18.70 trials, whereas a list of dissimilar adjectives required only 13.75 trials for learning. Manipulating trigrams by means of letter duplication into serial lists varying at three levels of similarity, Underwood (1952) also found ease of learning to vary inversely with level of similarity from low to high.

Higa (1963) manipulated associative and conceptual similarity in PA learning in several ways. The stimuli included in all the lists were 12 trigrams. In one list the response words were six pairs of antonyms (for example, *dark, light*), in another, six pairs of associates (*scissors, cut*), in yet another, six pairs of synonyms (*fast, rapid*), and in a fourth six pairs of coordinates (for example, *apple, pear*). Unrelated words were used in a control list. Lists in which the response members involved antonyms, synonyms, or coordinates were more difficult to learn than the control list. This presumably means that subjects had difficulty in determining which antonym, which synonym, or which coordinate of the two available in each list to pair with the appropriate stimulus. This is a case of interference, and in some instances (as with the associates) may have arisen because of implicit associative responses (see above).

Inter-item similarity, then, is a potent characteristic of materials in acquisition in verbal learning tasks. It seems to facilitate response learning but to hinder the learning of associations between particular responses and specific stimuli. This topic will be encountered again in the discussions of retention and transfer, with respect to similarity between lists. (For a more complete review of the literature and for the report of their experiments, see Goss and Nodine, 1965, Chapter 5 and Appendix.)

Counts

As is indicated in the introduction to this chapter, one of the secondary laws of association is frequency; that is, in the formation of associations the frequency with which the items are experienced together is a factor in their becoming associated. Frequency of occurrence is a variable which is easily manipulated in the laboratory, and many investigations, especially those concerned with retention over time, have included this variable as an important element. The whole notion of the incremental growth of habit strength, with each contingency between the stimulus and response adding some strength to the association between them, is a reflection of the law of frequency. One of the theoretical issues in the study of learning is whether frequency is a necessary and sufficient condition for the acquisition of an association. We do not enter into the discussion of this issue here but register the issue as an indication of why frequency has been considered as so important.

A notion closely related to frequency is that of familiarity. Presumably, frequently experienced items are familiar ones. Hence, ratings of familiarity are often employed instead of actual frequency counts to assess, essentially, frequency. The validity of such ratings is, of course, then of interest, and, to the extent that the ratings are valid, indicates that people have and can report information concerning frequency characteristics of their language.

Counts have been made of the frequency with which words, letters, and combinations of letters appear, usually, in printed sources and, occasionally, in records of speech. We discuss them first and some of their properties as well as indicating whether ratings of familiarity relate to frequency counts.

Word counts Although a number of word counts have been published in part or whole (see Goss and Nodine, 1965, p. 18, for references), the most important count is the one published by Thorndike and Lorge (1944). This count brings together data collected by Thorndike and reported in 1921 and 1931, a count made from magazines by Lorge, one made from books for juveniles, and a semantic count.[9] The collection was made by hav-

[9] The semantic count involved the determination of the apparent meaning of a word in context, and the meanings were classified by means of the list of meanings provided by the *Oxford English Dictionary*. A valuable abridgment

ing readers tally words as they read various kinds of texts, aggregating 4.5 million words for all of the counts. (The magazine count included only 1 million words [Thorndike & Lorge, 1944, p. 252].) The kinds of materials used by Thorndike included selections from sources as diverse as *Black Beauty, Little Women,* an issue of *The Youth's Companion, A Garden and Farm Almanac,* newspapers, and a book entitled *Pioneers of Australian Industry.* The sources for Lorge's magazine count were popular magazines, such as the *Saturday Evening Post, True Story,* and the *Reader's Digest,* published between 1927 and 1938. Similar sources were used for the other counts.

In the Thorndike-Lorge book itself, there are listed over 19,000 items which occurred once or more per million words. The frequencies are shown for each word in columns for the Thorndike (T), Lorge (L), juvenile (J), and semantic (S) counts. There is also a column headed "G," for general count. The G count is said to be "a summary from all four counts" (p. x) and is the one most commonly used. In it words that occur more than 100 times per million are simply designated AA and those occurring between 50 and 100 times per million as A; no actual frequencies are indicated for AA and A words. The book also includes lists of words occurring four times per 18,000,000 words. There are 30,000 words, altogether, in this volume, representing, probably, the words in most common use (at the time the tallies were done) of the roughly half-million lexical units in the English vocabulary that may be found in the *Oxford English Dictionary.*

Although quite out of date, the Thorndike-Lorge word list has been and continues to be useful and widely employed. Aside from its age, however, a further limitation on it is that it is based on printed English. There is some reason to believe that a word count of spoken English might indicate different word frequencies. Howes (1966) has published such a count, based on 250,000 spoken words recorded between 1960 and 1965. To obtain these data, interviews were conducted and recorded from 41 different subjects, 20 of whom were college sophomores and 21 of whom were patients hospitalized mainly because of bone injuries and peripheral nerve disease. The total number of different words he recorded was 9,699 of which 4,097 occurred only a single time each. So far, no use has been made of the Howes word count in studies of verbal learning, due to the fact that it has appeared so recently.

Before going on to indicate the significance of variations in word frequency to verbal learning, it is worth noting that there are a number of statistical relations in language behavior that appear in both spoken and written language and in a variety of languages. Among these are that a relatively small number of words from the total vocabulary occur with great frequency, whereas other words occur infrequently. In general, the frequently occurring words are shorter than the infrequently used words. There is much regularity in these and other statistical properties of language, although the speaker and the writer are probably not ordinarily aware that their verbal outputs obey these laws. (For further discussion and references, see Miller, 1951; Osgood, 1953.)

Word frequency is related to learning in certain verbal learning situations, although the available evidence is not extensive. Hall (1954) used four lists of 20 words each, presenting each list five times before asking for recalls. The lists varied, in Thorndike-Lorge frequency, from occurrences of 50 to 100 times per million words for the highest frequency list to one per million for the lowest frequency list. Recalls for the first of these lists averaged 15.04 words as against 12.04

---

of this work has been provided by West (1953). West's volume contains about 2,000 entries, and the meanings as well as the form classes determined for each word are recorded, together with their relative frequencies. For example, the word *man* (Rosenzweig & McNeill, 1962) is listed as having the following meanings with the percentage of occurrence of each in parentheses: *human* (10), *adult* (14), *male* (9), *soldier* (6), *servant* (1), *person* (54); all of these meanings are most likely nominal uses of the word *man.* However, the verb form also occurs 0.4 percent of the time.

words for the low-frequency list, a small but significant difference. There is a question, however, whether the difference reflects the variation in frequency or in inter-word association. As we know, free recall is greater for words that are associated than it is for words that are not associated. Deese (1960) verified Hall's findings but was also able to show that there were more inter-word associations in the case of high-frequency words than among low-frequency words. The differences in inter-item associations may, then, have been responsible for the relation of word frequency to recall, found by Hall.

In contrast, in serial-anticipation learning and in paired-associate learning it could be argued that associations between words should interfere with acquisition; we have seen evidence of this effect already. However, in serial-anticipation learning, a list composed of high-frequency words is learned more rapidly than one composed of low-frequency words (Underwood & Postman, 1960, Postman, 1961), and acquisition was faster in paired-associate learning when the response terms were high-frequency words than when they were of moderate frequency; the slowest acquisition occurred when low-frequency response words were to be learned. In contrast, when the word frequency was varied on the stimulus side, learning rate was best for words of moderate frequency. It is possible that associations between stimuli (for example, between *country* and *doctor*) may have handicapped paired-associate learning in the case of the high-frequency stimulus list.

It is worth noting that judgments of word frequency, which are like familiarity, correlate fairly well with the actual counted frequencies of the words judged. The judgments are highly reliable and are correlated with actual frequency at about .80 over five sets of words (Howes, 1954).

Letter, bigram, trigram, and other counts A number of counts have been reported for the frequencies with which single letters, bigrams, and trigrams occur in printed words (see Goss & Nodine, 1965, pp. 18–20, for references). The techniques employed are simply to select samples of so many words from each of a variety of printed materials such as magazines, newspapers, novels, encyclopedias, and the like. Single-letter counts are made by simply tallying occurrences of each letter as they are encountered in the material. Bigram and trigram counts are made as the following example illustrates: The word *Learning* contains the following bigrams, *Le, ea, ar, rn, ni, in, ng,* and the following trigrams, *Lea, ear, arn, rni, nin, ing*. Similar breakdowns would provide tetragrams such as *Lear, earn, arni, rnin, ning,* and pentagrams such as *Learn, earni, arnin, rning*. As each word is analyzed in this way, the resulting bigrams, trigrams, and so on, are recorded and tallies are made for frequencies of occurrence.

Single-letter frequencies are reported by Underwood and Schulz (1960, p. 69, Table 6), who also include data from other sources, and by Mayzner and Tresselt (1965). Mayzner and Tresselt report that a rank-difference correlation between the rankings for their total frequencies for single letters and the "U" count of Underwood and Schulz is .97. Mayzner and Tresselt report their frequencies not only as totals for a letter but also as number of occurrences in each position for 3-, 4-, 5-, 6-, and 7-letter words. Illustrative of their data is that the letter *A* occurs a total of 7,071 times in their sample of 20,000 words, as compared to 5,417 for Underwood and Schulz's sample of 15,000. It occurs 1,225 times as the first letter of a 3-letter word and only eight times as the third letter. These values may be compared to 129 times as the first letter and five times as the seventh letter in a 7-letter word.

In their Appendix D, Underwood and Schulz (1960, pp. 332–369) report frequency data for bigrams and trigrams. Mayzner and Tresselt (1965) report bigram frequencies (and their results again correspond well to those presented by Underwood and Schulz). Mayzner, Tresselt, and Wolin (1965a, b, c) provide

tables for trigrams, tetragrams, and pentagrams. These counts are also broken down for word length and position of the combinations in the words of different lengths.

When single letters are used as responses in paired-associate learning, and 2-digit numbers are employed as stimuli over 15 trials, more correct responses are made as letter frequency increases (Underwood & Schulz, Experiment 9, pp. 163–167, Figure 22). A similar but less regular relation is found between learning and frequency when bigrams are used as responses (Underwood & Schulz, 1960, pp. 167–169, Figure 23). Korn and Lindley (1963) studied the serial recall for strings of consonants, one string being composed of high-frequency consonants, the other of low-frequency consonants. Serial recall was better for the string of frequent consonants than for the string of less-frequent consonants. Mayzner and Schoenberg (1964) used the same sets of consonants to construct bigrams but arranged each set so as to manipulate bigram frequency. With the high-frequency consonants it was possible to arrange the letters so that bigram frequencies were high (H-H) and also so that the bigram frequencies were low (H-L). With the low-frequency consonants, it was possible to arrange only bigrams of low frequency (L-L). Over six strings of each type, the H-H list yielded 42.25 correct responses, the H-L string 32.50, and the L-L set 21.96 correct responses. Clearly, then, frequency of single letters and of bigrams has some relation to learning in PA learning and serial recall tasks.

With trigrams which vary in frequency, however, the relation to learning has been inconsistent and mostly of low or zero magnitude. Underwood and Schulz (1960) report eight experiments with paired-associate learning and one with serial-anticipation learning in which trigram frequency has been studied. Within the range where meaning (as estimated from *m*, av, and related measures) makes a difference to learning, no systematic relation between counted frequency (which Underwood and Schulz suggested was the variable underlying *m* and *av*, and so on) and learning was found when pronunciability of the items is taken into account. Although not all writers are agreed that pronunciability is a more important variable than frequency or *m* (Johnson, 1962; Noble, 1963, pp. 109–110), the data amassed by Underwood and Schulz on this score are impressive. We have more to say on this problem in the section on ratings. That the frequency of trigrams does not to relate to learning, independently of pronunciability, however, does not invalidate the relations we have seen between learning and single-letter frequency, bigram frequency, and word frequency. In addition, there are trigrams for which a kind of frequency is predictive of learning (Underwood & Schulz, 1960, pp. 279–280). These are consonant syllables or other items with low association values, which are difficult to pronounce. For them the summed letter frequencies predict learning, when alphabetical sequences are eliminated. Although pronunciability ratings also predict learning in these cases, Underwood and Schulz are able to argue that pronunciability, for these items, may depend on summed letter frequency.

Before leaving the question of frequency counts, it is worth mentioning that ratings or rankings of items for familiarity or frequency do reflect the actual frequencies obtained from counts. For individual letters, Attneave (1953) asked a large number of Air Force trainees to think of a newspaper clipping containing 1,000 letters and then to estimate for each letter of the alphabet the frequency with which it would appear. The judgments of frequency and the actual frequency of letters in one group correlated at .79 and in another at .88. Underwood and Schulz (1960, pp. 52–56) presented their subjects with a pair either of bigrams or trigrams and asked them to choose the more frequently occurring one; they found that the judgments, on the average, were more often correct than incorrect. In another study of trigrams (pp. 184–187) judged frequency was correlated with counted frequency at from .46 to .51. (See

also Mayzner & Tresselt, 1962; Mayzner, 1964.)[10]

A frequency theory of verbal discrimination learning Eckstrand, Wallace, and Underwood (1966) have proposed that frequency differentials are critical to verbal discrimination learning. In this situation, it will be recalled, two items are presented simultaneously or successively, and a subject is asked to indicate which one is correct (C) or incorrect (I). The argument made by Eckstrand and his coworkers is that "the cue for discrimination is the subjective difference in frequency of occurrence between the C and I item" (p. 567) in each pair. When the frequency difference reaches a 2:1 difference between C and I, it serves as a cue for the application of a rule by the subject, that is, the rule of always selecting the more frequent of the members in a pair.

There are several sources by means of which frequency may be established. On the first or guessing trial, for example, a subject reads each pair member, thus giving each member a unit of frequency from these "representational responses." Then, the subject chooses one pair member and pronounces it, adding another unit of frequency by means of this pronouncing response (PR). In order to build up frequencies in favor of the correct response (because learning occurs in this situation), it is also supposed that when the experimenter tells his subject what the correct response is, the subject will rehearse the correct response (RCR), which adds a frequency unit to the correct choice. The combination of frequency increments from these three sources will, ultimately, over trials, favor the C alternative. A fourth factor which may add to the frequency is, for the case in which items in the same or different pairs are associated, the occurrence of implicit associative responses (IARs). We have already discussed the role of IARs in verbal discrimination learning.

The theory described above fits data already in the literature and was, indeed, developed to account for these data. Eckstrand and his coworkers provide further data in support of the formulation. Systematic differences in the difficulty of learning were found when a given element was the correct alternative in two pairs, and when it was incorrect in two other pairs in the list. The difficulty was greatest for the case of an item that was right in one and wrong in another pair, next for the case of an item that was incorrect in two pairs, and least for the case of an item's being correct in two pairs; the last case was superior to a control condition. Because the same items were used in the different arrangements in the experiment by Eckstrand and his coworkers the results are presumably due to the sources of frequency outlined above and cannot be explained on the basis of *m*, pronunciability, and other similar factors.

Ratings

It is possible to rate or to rank verbal units in a great many ways. We have already discussed several kinds of ratings, including those used as alternatives to production measures and frequency counts, for example. In this section other dimensions are mentioned, their relations to learning scores are summarized, and their intercorrelations will be described. Finally, we can raise the question whether these several dimensions are really different or whether in fact they represent alternative ways of assessing the place of verbal units on some more basic or underlying dimensions. Goss and Nodine (1965, pp.

[10] Familiarization procedures are a way of studying frequency experimentally. Basically, they provide for experience with the list items or with the stimuli or the responses of the items before the items are arranged in a list for actual learning. The results of experiments involving familiarization have been summarized by Goss and Nodine (1965, Chapter 6). Unfortunately, the effects of familiarization, as carried out in a number of experiments, have been inconsistent. That is, sometimes familiarization facilitates, sometimes inhibits, and sometimes has no effects on learning. Goss and Nodine (p. 178) say of these results, "at the present time . . . factors responsible for inconsistencies cannot be specified. . . ." Despite the interest and the importance of familiarization to verbal learning, the topic will not be discussed here because of the inconsistent findings.

20–59) have provided a comprehensive review of this topic.

In addition to familiarity and scaled meaningfulness, which are discussed above, the following dimensions or attributes have received some study.

Ratings of learning speed Underwood and Schulz (1960, pp. 19–21) obtained ratings of 96 words on a 9-point scale ranging from Difficult to Easy to learn. The ratings were made in the context of 10 words which each subject was asked to inspect first and which covered the range of *m* values obtained for dissyllables by Noble (1952). The 96 items used were Noble's dissyllables. The correlation of the ratings with the *m* values was .90. A parallel study on 90 nonsense syllables yielded an *r* of .86 between ratings for ease of learning and ratings for the number of associations each syllable would evoke. After completing the ratings, Underwood and Schulz asked their subjects to indicate what factors they had used in making their ratings for speed of learning. Three were mentioned most prominently—associations an item suggested, the familiarity of an item, and how easy it was to pronounce.

Ratings of a similar kind to those described above have been obtained for pairs of stimuli. Richardson and Erlebacher (1958) asked one group of subjects to rate the association or connection between the members of each pair, and asked another group of subjects how easy it would be to learn the second member of a pair as a response to the first member as stimulus. For words, nonsense syllables, and CCCs the two sets of ratings were very highly correlated (rho = .96). Battig (1959, 1960) obtained ratings of the ease with which pairs of nonsense syllables could be learned from a restricted range of Glaze *av* (47–53 percent). Despite the homogeneity of these items for *av*, the mean ratings for the pairs covered a wide range over a 9-point scale. His values, however, correlated .69 with the average Archer *av* for the members of each pair.

Occurrence as words When CVCs (consonant-vowel-consonant units), which had been scaled for meaningfulness (*m'*), are inspected to see how many are actual 3-letter words, it is found that the relative frequency of words increases with *m'* (Noble, 1963, p. 90, Figure 4-4, p. 91; Noble cites other references on this question). For example, over 90 percent of the items rated at above 4.0 on *m'* are words as compared to approximately 10 percent of those rated at about 2.75 on *m'*.

Pronunciability Underwood and Schulz (1960, pp. 23–25) used a 9-point scale for ratings of the pronunciability of trigrams, including words, CVCs, and CCCs. Each subject was asked to attempt to pronounce each trigram to himself before rating it. (Pronunciability ratings for 239 trigrams are given in their Appendix E, pp. 370–372.) There was a correlation of .78 between these ratings and *m'* values for the CVCs (100 of the 178 items), and, for 86 CVCs, the correlation between *m'* and judged speed of learning was .92.

Underwood and Schulz (1960, pp. 185–187) obtained the following measures for 36 trigrams: counted frequency, rated frequency, pronunciability ratings, and learning scores, and they computed intercorrelations and partial correlations for these measures. The correlations between rated frequency and counted frequency ranged from .46 to .51, between rated frequency and pronunciability from .73 to .79, between pronunciability and learning from .76 to .82, and between familiarity and learning from .68 to .69. Clearly, pronunciability is the best predictor of learning, and it is more closely related to rated frequency than is counted frequency. As we said in the last section, counted frequency does not relate well to learning scores, independently of pronunciability, and we have seen that, among the predictors used by Underwood and Schulz, pronunciability, for trigrams in the range between words and poorly integrated CCCs, is the best one so far as learning is concerned. Pronunciability does not correlate well with counted frequency.

Johnson (1962) has questioned whether pronunciability is as basic a variable to learning as Underwood and Schulz suggest that it is. He classified response members (trigrams) in paired-associate learning as words, syllables, and nonsyllables and found that the number of correct responses decreased in this order. For each class of item, Johnson split the items at the median for pronunciability. He found no difference in the number of correct responses made for any class between items above and below the median for pronunciability.

Affectivity We said above that the emotionality of stimulus words is a factor in the properties of word association distributions. In this section, we are concerned with ratings of emotionality over a range of emotionality, rather than simply the comparison of emotional and neutral words, and we are also interested in whether these variations in emotionality are related to other properties of the verbal items.

Noble (1958a, b) had subjects rate his 96 dissyllables by placing each in one of four categories, neutral, pleasant, unpleasant, or mixed, and weighted these categories from 1 to 4 respectively. He found a correlation of .57 between these values and *m* (see also Strassburger and Wertheimer, 1959), but Underwood and Schulz (1960, pp. 151–152), embedding 27 of the dissyllables among 34 words which had more pronounced affective characteristics, obtained an *r* of only —.300. Ratings of goodness and badness of words have been obtained by Johnson, Thomson, and Frincke (1960) and Johnson, Frincke, and Martin (1961). Johnson, Weiss, and Zelhart (1964) found higher *m* for "good" than for "bad" words (see also Howe, 1965). Keppel (1963) found that correlations between ratings of goodness and Noble *av* are high. However, pronunciability and goodness were also highly correlated and, when the effects of pronunciability were taken out by partial correlation, goodness and *av* became insignificantly correlated.

Other kinds of emotional ratings of words have been reported—for example, for aggressiveness (Buss, 1961)—but little systematic work on them has been carried out. Furthermore, in most of the investigations in which emotionality of words has been studied, other characteristics such as *m* or *av* have not been controlled. Thus, it is difficult to know to what variable to attribute any differences that are found (see Goss & Nodine, 1965, pp. 71–72, fn. 2).

Semantic differential In the semantic differential, words or other concepts are rated on 7-point scales, the extremes of which are anchored by bipolar adjectives (for example, *good-bad, hot-cold*). Jenkins, Russell, and Suci (1958) have reported mean ratings on each of a number of scales for 360 words. Koen (1962) obtained *m* values and scores on 12 semantic differential scales for two lists of 15 emotional and 15 neutral words each. He found correlations between the degree of polarization of the semantic differential ratings with both *m* and counted frequency for neutral words, but the correlations were zero with *m* and were reduced with frequency for emotional words. Jenkins (1960) has reported a relationship between *m* and polarization; a small correlation between these variables has also been reported by Wimer (1963). There are also correlations between polarization and frequency (Koen, 1962). Unfortunately, the semantic differential ratings have not, apparently, been studied with respect to acquisition in verbal learning situations.

Pairs of stimuli We have already mentioned, in discussing similarity between items, that scalings of pairs of items have been reported for synonymity. Haagen (1949) also provides ratings on vividness and strength of association. Haun (1960) used a paired comparison technique to determine the strength of the association between items; he suggests this method as an alternative to obtaining

associations. Jenkins, Russell, and Suci (1959) present values for similarity of meaning in terms of semantic differential values for each of 360 words paired with every other word. Flavell (1961) obtained evaluations for the probability of 2 objects, events, and the like occurring together in the real world, as well as estimates of the similarity of meaning of the items in each pair. Their occurring together and their similarity of meaning were highly correlated; adding a measure of similarity from the semantic differential did not raise the relationship further. Flavell and Johnson (1961) studied similarity, further, with associational techniques. Aside from Haagen's ratings, little work has been done with these measures in actual learning situations (see Goss & Nodine, 1965, pp. 102–103).

Comment As may be seen from the findings summarized in this section on ratings, many of the ratings are correlated with others or with *m, f, av,* and the like. Spreen and Schulz (1966) have published ratings for 329 nouns on 7-point scales for specificity and concreteness, as well as *m* values. They also computed intercorrelations among these measures, along with pronunciability. Specificity (*s*) and concreteness (*c*) are highly correlated (.63), and *s* and *c* are correlated with *m* (.56 and .70, respectively). Pronunciability was not highly related to these measures. So far as *s, c,* and *m* are concerned, Spreen and Schulz (pp. 465–466) conclude "that the interrelationships . . . are sufficiently strong that in an attempt to manipulate one of them in a perceptual and/or learning situation all others will have to be controlled, if analytic conclusions regarding the effects of the manipulated variable are to be ascertained."

Unfortunately, it is not possible, despite all the strong, positive correlations that have been found among measures of properties of verbal material, to say which one or ones are basic to the others or whether none of these measures is itself basic but rather that there is some more fundamental dimension which underlies them all.

PROPERTIES OF VERBAL MATERIALS: CONNECTED DISCOURSE

In actual language, whether spoken or written, which we here designate by the term *connected discourse,* any given word no longer appears in the degree of isolation from others that is characteristic of list-learning, association tests, rating procedures, and counts. No word is perhaps ever completely isolated from others even in these situations (Deese, 1961), but in connected discourse there is no question of isolation. This is because ordinary language is structured in ways that are not ordinarily reflected in experiments involving the learning of lists. In this section we attempt to describe some of the ways in which the structure of connected discourse has been described.

In the history of the study of verbal learning, connected discourse entered at the beginning. Ebbinghaus learned poetry, as part of his study on memory, and many other investigators have reported observations on the learning of poetry and prose. However, investigations of the learning of connected discourse have been handicapped by two problems. One is the problem of scoring achievement in learning and retaining connected discourse. Because this problem is essentially the one of finding suitable units in terms of which recall can be scored, it is closely related to the second problem: How may the structure of connected discourse be conceived? Two kinds of answers have been given to this second question, which will be considered after the scoring problem.

The Problem of Scoring

In writing or speaking, one can often say the same thing in several ways. To say, "The ball was hit by the man" is tantamount to saying, "The man hit the ball." The problem of scoring is to evaluate the equivalence of these two expressions and to evaluate the equivalence of other expressions which are less synonymous than these. Such problems

arise when we wish to measure the subjects' recall in terms of the content, the sense, the ideas, or the substance of what the passage contained. There are also problems when verbatim reproduction of the passage is required. In the example given above, shall order be considered? The noun phrase, "The man," occurs in both sentences, but at opposite ends. So also with "The ball." Problems like these beset anyone who wishes to score recalls of connected material.

King (1960; King & Schultz, 1960; King & Yu, 1962) has made some direct studies of the scoring problem. In doing so, he began by developing a judgmental criterion for the adequacy of the recall. He first collected a number of recalls of a story and then employed judges who were to scale each for accuracy by comparing it with the original passage. He found that judges agreed with one another very well in the judgments they made. He was then able to study the validity of other scoring methods, using the judged accuracy of the recall as a criterion. King has used several such measures and has employed factor analyses of correlational matrices for the measures and the criterion in order to define the dimensions on which recalls might vary. He has repeatedly found that the matrices yield two factor solutions, and the factors tend regularly to be (1) a quantitative one, indexed by total number of words recalled or number of identical content words in the recall and in the passage and (2) an organizational one, indexed by sequences of words identical in the recall and in the original passage. King's work gives promise that the problem of scoring recalls can ultimately be solved.

The Structure of Connected Materials

Connected materials have two main properties that have been studied in the laboratory: the sequential dependencies in connected material and their grammatical organization. The two properties are not unrelated.

Sequential dependencies or redundancy When we hear someone speak, we are often able to anticipate what he will say before he says it. Thus, if someone says, "The ball," we are likely to expect that he will go on to say "and the bat" or that he will follow the initial phrase with the verb "is" and continue with "red," "large," "round," among other things. It appears that there are two kinds of redundancy here. One is that after a noun phrase like "The ball," we are more likely to use a verb (*is, rolled*) or a conjunction (*and*) than we are to use another noun or an article. In other words, the choice of the form class of a word to follow another one is not free but, rather, is partly determined by what has gone before (and what may come afterward, as in "The ball slowly rolled . . ."). This is no doubt one basis for our ability to anticipate what a speaker will say, if, as speakers usually do, he follows one form class with another one in an ordinary way. The other kind of redundancy is semantic. Having said, "The ball and the," the speaker is unlikely to say "dog," "desk," "curtain," "machine" or "spinach," but he is likely to say "bat" or "glove." This is to say that the selection from within a form class (for example, nouns) is limited by what is said. The sentence, "The card was placed in the box," contains both sources of redundancy. If we scramble these words, as in "Box the in card the was placed," we have destroyed the ordinary sequence of the form classes. However in the following sentence, "The card was shining in the pencil," we have lost the redundancy arising from semantic relations, while preserving an ordinary sequence of form classes.

To study the role of sequential factors in recall of connected discourse, Miller and Selfridge (1950) developed passages in the following way, calling them approximations to the English language. A second-level approximation was developed as follows. Let us choose a word, any word, say, *watch*. Then we ask a subject to give a sentence including

this word. He says, "The watch keeps good time." We then take *keeps* and ask another subject to use it in a sentence. He provides, "The boy keeps water in a bottle." Giving the next subject *water,* we get from him "Water those plants!" Using now just the first words generated by each subject, we have *keeps, water, those,* a sequence in which each word was provided in the context of one other word appropriately used in a sentence. Miller and Selfridge developed strings in this way for several passage lengths and also for several amounts of context, by using, for example, 3, or 4, or 5, or 7 words in the context of which a person was told to add one in a sentence. A first-order approximation was obtained by scrambling words of the other orders, and a zero-order approximation by taking words at random from a dictionary.

Miller and Selfridge obtained recalls for strings of words of varying length and different approximations to English. In general, they found an effect of both variables on recall; that is, the recalls were better for higher orders of approximation, especially with the longer strings (up to 50 words). Deese (1961) has indicated that this increase in recall may, however, be due not to better recall as such but rather to an ability to "reconstruct" what must have been in the string for the high approximations. Thus, in the zero-order list there are hardly any function words (articles, preposition, pronouns), whereas in the higher orders there are. Thus a subject can improve his recall of the latter, but not the former, by inserting a few function words in his "reproduction."

Grammatical organization There are several ways in which grammar enters connected discourse. One is in terms of "tags" that tell us, in some cases, what kind of word a word is. Thus we pluralize nouns, often by adding "s" or "es," make the past tense of many verbs by adding "ed," often make adverbs by adding "ly" to a stem, and make the comparative and superlative forms of some adjectives by adding "er" and "est." The parts of speech themselves are a part of grammar. Perhaps more important is the fact that sentences are organized in certain ways and never in others and the fact that some words go together whereas they do not go with others.

Epstein (1961, 1962) added certain grammatical features to a string of nonsense syllables. Thus, the string "yig wur vum rix hum jeg mir" in one arrangement was preceded by the article "The" and the preposition "in" was inserted between "hum" and "jeg." In another, the following was used: "The yigs wur vumly rixly hum in jegest mir." Epstein found this last arrangement to be easier to learn than others. He also found that a nonsense sentence, which preserves ordinary grammar, such as "Cruel tables sang falling circles to empty bitter pencils," was easier to learn than a random string of the same words (see also Marks & Miller, 1964).

Glanzer (1962) used paired-associate learning to study the learning of words representing form classes. In one arrangement he used word-CVC pairs and in the other CVC-word pairs. When the words were content words (nouns, verbs, adjectives, adverbs), learning was more rapid than it was when the words were function words; also the CVC-word pairs were easier to learn than the word-CVC pairs, reflecting, probably, the relative roles of response- and stimulus-*m*.

In the case of the sentence, "The boy read the large book," it is obvious to speakers of English that the sequence "read the" is not a unit in the sense that "The boy" is a unit. Some words are related to one another in a sentence whereas other words are not so related. In linguistic descriptions called "phrase structure grammars" (Chomsky, 1957), we can represent a sentence like the one just given as being composed of a noun phrase and a verb phrase and further decompose these units to show which words are interrelated and which are not. Thus we may write as follows:
Johnson (1965) has shown that the division of a sentence into its constituents is reflected in learning. He made up eight pairs, each composed of a digit and a sentence. The subject's task was to learn to say a sentence when he saw the digit that had been paired with it. Johnson analyzed the errors made in the recall of the sentences. To do so, he measured the "transitional error probability." Given the correct recollection of one item, say, *boy*, what is the probability that the next element (*read*) will be recalled? The answer to this question is the transitional error probability or TEP. Johnson found, essentially, that more TEPs were given at points of transition between major components of sentences (for example, between the noun phrase and the verb phrase) than within components, thus lending support to the notion that the phrase structure of a sentence is related to the way in which it is learned. Johnson used sentences more complex than our example given above, such as "the house across the street is burning."

The sentences we have used as examples so far are relatively simple, active, affirmative, declarative sentences. There are many other sentences in the language, such as "The large book was read by the boy," "Is the boy reading the large book?," "Is not the boy reading the large book?," "Was the large book read by the boy?," and many others. Chomsky (1957)[11] has suggested that these sentences are achieved by transformations of an underlying structure of such sentences. The simplest transformations yield the simple, active, affirmative, declarative sentences, and other transformations alone or in combination produce the more complex sentences (see Miller, 1962). Mehler (1963) has reported evidence suggesting that complexity of transformation may be involved in the learning rate for sentences. The major difference he obtained, however, was an advantage for the simple, active, affirmative, declarative sentence as against others.

The topic of grammatical organization has only recently entered the study of verbal learning, and it is perhaps too early to tell whether linguistic descriptions of this organization will have systematic relations to characteristics of the learning of connected discourse.

[11] Later developments in Chomsky's analysis are not entirely consistent with this statement, but it is beyond the scope of this chapter to follow these developments further (see Chomsky, 1966).

Richard B. Millward

THEORETICAL AND EXPERIMENTAL APPROACHES TO HUMAN LEARNING*

20

INTRODUCTION: THE NATURE OF THEORY

In this chapter, four basic human learning procedures will be described, along with some current techniques and theories used for analyzing these procedures.[1] The procedures are probability learning (PL), concept learning (CL), paired-associate learning (PAL), and serial learning (SL). To a certain extent, this chapter also provides an introduction to quantitative theories in experimental psychology, but with the restriction that all examples are of human-learning paradigms. Specific models developed in close conjunction with data are constructed for each experimental routine.

In all the material discussed below there is a mixture of empirical results, procedure, and theory. Unlike some areas of psychology and much of the material in sciences such as physics, chemistry, and biology, the role of theory is often considered to be a controversial rather than an accepted interpretation of the facts. For this reason, some discussion of the role of theory

*Preparation of this chapter was supported in part by Grant No. MH 11255 from the National Institutes of Health to the author, Richard B. Millward. The author wishes to express a special thanks to his wife, Celia, who despite her own professional and family duties has provided editing help throughout the preparation of this chapter.

[1]The coverage of human learning is not intended to be comprehensive but in so far as space permits, a complete coverage of the 4 paradigms is made.

in science seems pertinent at this point. We often find it difficult to think of a theory as a hypothesis about the empirical world; instead, we tend to think of a theory as a factual statement about the empirical world. However, theories are a combination of the obvious, the proved, and the possible. They begin by dealing with the obvious; if they are to be accepted, they cannot contradict what is patently clear to ordinary observation (although what is patently clear is not always independent of theory and sometimes the obvious must be demonstrated). As a theory is elaborated, new principles, new interpretations, and new rules for application are developed. These often require experimental support. But even a very well grounded theory, one with a large number of reliable statements accounting for empirically observed relationships, has implications that are merely possible and thus could be proved wrong. The working scientist sometimes loses sight of this distinction between the empirical world and the theoretical statements made about it.

A theory begins when we posit some givens, the primitive terms. Next, we assume that relations exist between these givens; these relations form the axioms of the theory. From the given primitive terms and axioms, we can derive new relationships by a deductive process. An important requirement at this level is consistency; that is, no two deductions can be contradictory. Because any set of axioms of reasonable complexity has a large number of possible deductions, we cannot always state all the possible deductions. In such cases, we can demonstrate the consistency of the set of axioms by showing that a model exists. A model is a realization of the set of axioms that uses all the axioms. If a model exists, the set of axioms is consistent, for the impossible cannot exist. This is a rather technical definition of a model introduced by philosophers of science (see Suppes, 1957; Nagel, 1961). For our purposes the simpler, less exact distinction suggested by Atkinson, Bower, and Crothers (1965, p. 6) will do just as well. "A model is viewed as a special case of a theory. Theories are general formulations that are applicable to more than one class of phenomena. Restrictions on the general theory lead to specific models for particular experimental situations." At this point we have a theory, but we still have not determined whether or not it is a theory of any empirical phenomenon or process. To make the theory a working theory, we must make statements relating the primitive terms and axioms to the empirical world. In the original statement of a theory, these relationships are usually implicit.

The first statements of a theory properly handle only a limited set of empirical relationships. However, by deduction, new statements about the empirical world are made. If, by experimentation, these statements are found to be adequate, the theory is strengthened. Often a theory is said to be proved, but such an assertion is too strong, for there are often other statements yet to be tested. If and when additional deductions prove erroneous, modification of the original theoretical structure or of the rules for applying the theory must be made. Gradually, by deductions, tests, re-evaluation, and continual restructuring of the theory, a theoretical statement of broad applicability and high reliability evolves. The important points are as follows.

(1) The primitive terms and axioms of a theory should be as clear and as independent of empirical content as possible.
(2) The rules for applying the theory should be clearly stated.
(3) Deductions should be made by logical or mathematical rules that limit the role of intuition as much as possible.
(4) The deductions of the theory must be experimentally tested.

There have been thousands of experiments run according to the four paradigms of this chapter. In a great many cases, the interest of the experimenter was purely empirical. These are the "let's see what happens" kind of experiments. More often, to varying ex-

tents, the researcher was interested in demonstrating the correctness of some deduction from a theory or in showing the error in some tenet of a theory. Because premature theorizing has led many a researcher astray, there is often strong criticism against theorizing of any kind. Both the operant approach (see Skinner, 1950, "Are Theories of Learning Necessary?") and the functionalist approach have stated this position strongly. Although their arguments are cogent, the importance to science of a clearly stated theory must not be overlooked. Whether a scientist cares to theorize or not, he usually has some implicit conceptualization of the process. Insofar as this conceptualization can be made explicit, critical tests of basic assumptions can be made. In any case, the literature related to PL, CL, PAL, and SL is heavily dosed with theory and because our goal is to understand this literature, we are forced to deal with theory.

PROBABILITY LEARNING

During the 1920s, 1930s, and 1940s, maze learning was the most important experimental procedure for many theoreticians and experimenters. Indeed, in the revised edition of Woodworth and Schlosberg (1954) there is a complete chapter on maze learning. However, since the 1950s, the interest in complex mazes has diminished, while probability learning has played an increasingly larger role in research. Probability learning has one of its roots in maze learning—it is analogous to a maze with a single choice point. More recently there has arisen an area of study concerned with choice behavior, which treats only the behavior of subjects at the point during which a choice is made. Now, although PL concerns learning, on any given trial the subject is making a choice. Thus, there is actually a great deal in common between work in PL and in choice behavior. However, because there has been so much study and literature produced that is solely concerned with PL, we must of necessity omit dealing directly with the choice paradigm. The reader is referred to two excellent articles for this area: Bush, Galanter, and Luce (1963), and Luce and Suppes (1965).

Some authorities on human rote learning argue that PL is not an instrumental learning procedure. Underwood (1966), for example, includes it under classical conditioning. Other theorists consider it a form of concept learning (see Goodnow, 1955; Galanter & Smith, 1958; Feldman, 1963). However, because most studies in probability learning have been with human subjects, there is good reason for including it under human learning. Further, this chapter emphasizes theory, and PL has served as the main experimental procedure for testing statistical learning theory.

Historical Background

During the 30 years from 1920 to 1950, most of the theoretical work related to verbal learning or rote learning was derived from work done on animals, in the belief that there was a simple hierarchical structure to learning. It was felt that basic laws and principles had to be developed first and that these laws could best be discovered using animals as subjects. Once established, these laws could be applied to human learning. Therefore, researchers studying human learning became either pure functionalists, and did not enter into the debates and controversies of such prominent theoreticians as Hull, Guthrie, Tolman, and Skinner, or else they ran a conditioning type of experiment involving nonsense syllables and humans. McGeoch and Irion (1952) summarize the state of work up to the decade of the fifties.

Statistical learning theory (SLT), basically a quantitative description of many of the principles worked out during the first half of the century, bridges the periods before and after McGeoch and Irion. SLT also represents the beginning of the quantitative theorizing that has taken place since 1950. Few people today believe that SLT adequately describes all aspects of PL, and even fewer believe that it can be applied in its early form to paired-associate learning, concept learning, or serial

learning. Nonetheless, even its shortcomings are important, for they have pointed to new approaches and concepts.

Humphreys (1939) introduced a variant of classical or Pavlovian conditioning for humans that he called *verbal conditioning*. The name of the routine indicates what earlier investigators considered it to be—a form of classical conditioning.[2] In the classical paradigm, a signal (the conditioned stimulus or CS) is given, followed soon afterwards by a strong response-producing stimulus (the unconditioned stimulus or US). The initial response to the signal is usually minimal, but eventually a response resembling the unconditioned response to the US occurs following the CS. For example, in Humphreys' version of verbal conditioning, subjects are instructed to predict whether or not a light will occur on each of a series of trials. Each trial begins with a signal (the CS); then the light either is flashed on or is not. The light is assumed to be the US; presumably, it will evoke a strong expectancy response. After a number of trials, the signal itself will also evoke the expectancy response, and conditioning then is said to have occurred. The simple piece of equipment (now called a Humphreys board) that Humphreys used to run subjects in this basic design consists of a vertical board with two lights and a telegraph key for the subject to press. One light acts as the CS and the other as the US.

Estes and Straughan (1954) noted that, in the conditioning version of Humphreys' design, a failure to respond could mean that (1) the subject did not expect the light to be turned on, (2) the subject delayed too long, or (3) the subject simply did not care. They varied Humphreys' procedure by introducing two lights and two response keys and instructed subjects to predict on each trial which light would go on by pressing the corresponding key. They used a probabilistic reinforcement schedule, that is, on 70 percent of the trials, the left light went on, and on 30 percent of the trials, the right light went on. Estes and Straughan confirmed a result previously noticed by Hake, Grant, and Hornseth (1951). Subjects predicted the left light and the right light with the same frequency as these lights were reinforced, that is, 70 percent and 30 percent, respectively. In other words, they matched probabilities. Today, there are some questions about the exactness with which probabilities are matched, but in any case deviations are not large. However, probability-matching does not maximize correct responses, a fact that has produced some serious theoretical arguments.

The experimental verification of probability-matching was made just after Estes (1950) had developed the preliminary structure for statistical learning theory (SLT). Estes then showed that SLT predicted probability-matching on the basis of some very simple assumptions about the conditioning process (Estes & Straughan, 1954). Probability learning and statistical learning theory were thus wed; since that time, the majority of PL studies has been run in order to test SLT and SLT has most often been tested by a PL experiment.

Prior to the work of Estes, some of the basic tenets of SLT had been expressed in a much less formal manner by Guthrie (1935, 1959; see also pp. 560; 567 ff.). Three important ideas are central to Guthrie's theory. The first is that all learning takes place by a contiguity principle rather than a drive-reduction principle. That is, no need or drive has to be reduced for learning to occur. All that is necessary is that a stimulus and a response occur together, or, more exactly, that the desired response be the last one made in the presence of the stimulus. When this is the case, the stimulus, on its next occurrence, will evoke the same response. Guthrie's second principle is that the strength of such an S-R bond is either zero or at a maximum. There are no intermediate degrees of strength. The third principle is that most observed and measured stimuli and/or responses are not unitary but

[2]Today the term *verbal conditioning* is generally reserved for a variant of operant conditioning (see Verplanck, 1955; and Greenspoon, 1955).

are composed of a number of simpler, more elementary components. Thus, a stimulus, such as a tone, is composed of a large number of elementary stimuli, and a response or act, such as pressing a key, is composed of a number of simpler movements. The all-or-none connection of a stimulus and a response by contiguity alone is true at the elementary level for stimulus components and response movements but not for gross stimulus compounds and response acts. Thus, gross stimuli and responses, being composed of a number of elementary units, are connected only by repetition, which gradually connects all the elementary units.

To what extent Estes was influenced by Guthrie is difficult to say, although he does give explicit credit to many of Guthrie's ideas (see Estes, 1959b, p. 399). Certainly the basic ideas of the stimulus as a set of elementary stimuli, the all-or-none connection of each stimulus element to some response (Guthrie did not make it explicit whether or not an element always had to be connected to some response), and the simple requirement of contiguity only are present in both theories. However, to conclude from this similarity that SLT is merely a mathematical formulization of Guthrie's ideas would be erroneous. The crucial added ingredient is the use of probability theory and the commitment to the probability of a response as a dependent variable.

Basic PL Paradigm

In a typical PL experiment, the subject sits facing two outcome lights with two response keys directly below them. Between the two lights, but slightly elevated, there is a signal light. A trial begins when the signal light is turned on for about 2 sec. During this time, the subject is to press the key under the outcome light that he thinks will come on. Following his response, one of the outcome lights comes on for about 1 or 2 sec. Then, about 2 sec later, the signal light is turned on again. In a noncontingent PL experiment, the outcome on one trial does not depend on the outcome on any other trial. (In probability theory, such a sequence is known as a Bernoulli sequence.)
Figure 20.1. Trial paradigm for noncontingent probability learning. S signifies signal. P_n is an abbreviation of the probability of an A_1 response on trial n, $P(A_{1,n})$. The outcome probability, $P(O_{1,n}) = \pi.O_{i,n}$ represents the ith outcome on trial n, and $E_{i,n}$ is the assumed reinforcing event associated with the $O_{i,n}$ th outcome.

Figure 20.1 provides some of the symbolism necessary to discuss the noncontingent experimental routine. The two outcome lights are labeled O_1 and O_2 to indicate outcomes 1 and 2. The subject's corresponding responses are labeled A_1 and A_2. (The values of $E_{i,n}$ will be discussed later.) The basic independent variable in PL is the probability that one or the other of the lights will be turned on. Let $P(O_{1,n}) = \pi_n$, that is, the probability of an O_1 outcome on trial n. In most studies, this probability is the same for all trials and thus the subscript is dropped (that is, $P(O_{1,n}) = \pi$). Further, because we are concerned here with a noncontingent PL experiment, O_1 is determined probabilistically and independently of the subject's response. Finally, P_n refers to the basic dependent variable, the probability of an A_1 response on trial n, $A_{1,n}$. There is no direct measure of P_n, so it must be inferred from the results of the experiment. Such an inference depends on what assumptions we make; for this reason, a theory of PL is necessary.

Before considering the application of SLT

to PL, some details about running such an experiment should be presented. First, the experimenter must generate the outcome sequence. For example, if $\pi = .7$, he could consult a table of random numbers and pick an O_1 outcome when a digit between 1 and 7 is observed and an O_2 outcome when the digits 8, 9, or 0 occur. Or, to insure exactly $.7N$ O_1 outcomes per block, he could randomize within a block of N trials by picking $.7N$ numbers from the numbers 1 through N. Fixed-block randomization, however, is often avoided because it restricts the distributions of outcome runs, thereby raising certain theoretical problems. The experimenter must record each outcome and each subject's corresponding response for the trial. The resulting data protocol consists of a numbered sequence of O_1 and O_2 outcomes, along with a sequence of A_1 and A_2 responses for each subject. Usually, 10 to 20 subjects are run under exactly the same conditions except for outcome sequences. If each subject cannot be presented with a unique sequence, two or more subjects may be given the same sequence. Normally, over 200 trials are run; in more recent experiments, up to 1,000 trials have been run.

Theoretical Analysis

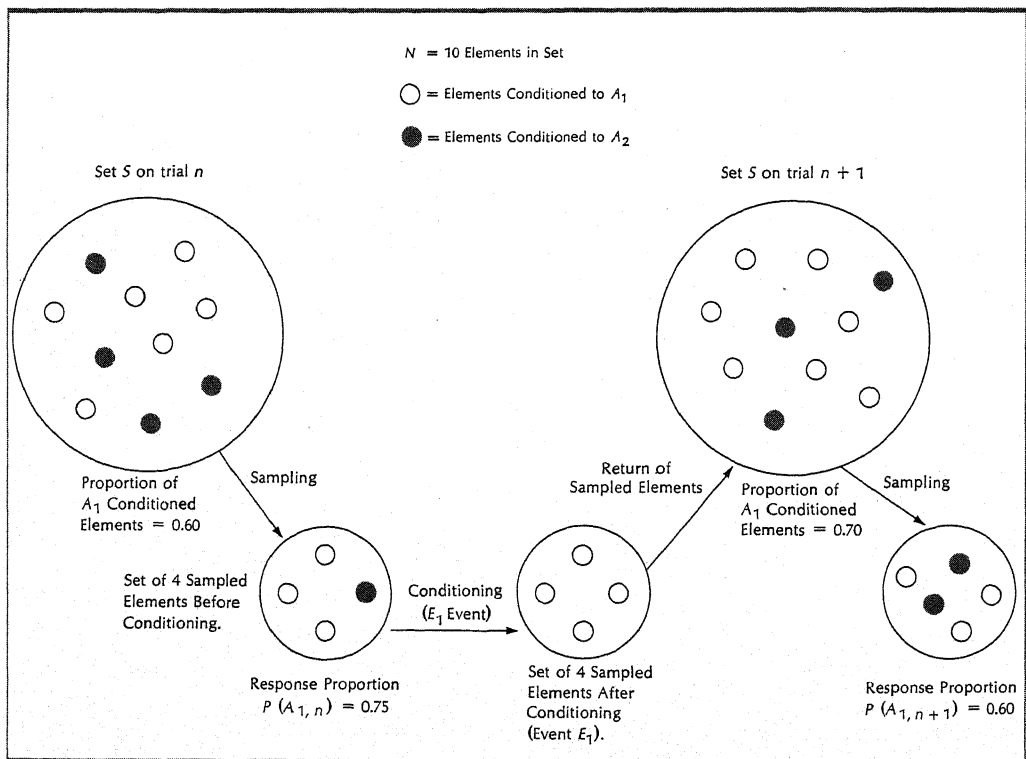
Axioms Properly speaking, SLT is not one single theory. Here, we use the term SLT for the early version of the theory as described by Estes (1959b). Estes gave a detailed discussion of the theory in which he also presented his own view of how it was developed. All the many versions or elaborations of this early structure are usually called *stimulus sampling theory* (SST). Much of the theoretical work in PL has been done using a mathematical


Figure 20.2. Schematic diagram showing the axioms of SLT in operation. One trial with an E_1 reinforcing event is illustrated. (See text.)

approach developed by Bush and Mosteller (1955), which does not require the stimulus-sampling assumptions of SLT. But there has been a great deal of mutually beneficial interaction between the stochastic learning theorists and the stimulus-sampling theorists. SLT as considered here consists of four sets of basic axioms (see, for example, Estes & Suppes, 1959; Atkinson & Estes, 1963; Atkinson, Bower, & Crothers, 1965).

1. *Representation Axioms*
   a. The stimulus environment consists of a set S of N stimulus elements.
   b. There are r mutually exclusive and exhaustive responses, $A_1, A_2, \ldots, A_r$. One and only one response is made on each trial.
   c. Each response A_i has a reinforcing event E_i. A neutral reinforcing event E_0 may also exist. One and only one reinforcing event is given on each trial.
2. *Conditioning Axioms*
   a. Each element of S is conditioned to one and only one response.[3]
   b. An element that is sampled on a trial becomes conditioned automatically to the reinforced response of that trial (to A_i if E_i occurs). Its previous conditioning status is lost.
   c. An element that is not sampled on a trial remains conditioned to its previously conditioned response.
   d. The E_0 event leaves sampled elements conditioned in the same way as before the trial.
3. *Stimulus-Sampling Axioms*
   a. On each trial, each element i has a probability θ_i of being sampled. Sampling produces a subset of S. It is usually assumed that $\theta_i = \theta_j = \theta$ for all i and j.
   b. On each trial, all sampled elements are returned to the total set of elements.
4. *Response Axiom*
   a. The probability of an A_i response on a trial equals the proportion of sampled elements conditioned to the A_i response.

[3]La Berge (1959) has introduced a variant of SLT which does not make the assumption that all elements are conditioned at the beginning of an experiment. Some are neutral and become conditioned as they are sampled and reinforced.

Figure 20.2 is a simple schematic diagram that illustrates how these axioms function to produce learning in the two-response ($r = 2$) situation. On trial n there is a certain proportion of elements in S conditioned to A_1. We can call this proportion p_n. If we make the simplifying assumption that all θ_i are the same, the average sample size will be θN. (At this point, the student should work out the following example: Assume $N = 3$ and $\theta = .6$. What are all the possible samples? Is the average size 1.8? With a small N, the probability of not sampling any elements remains relatively high and causes trouble with the sampling axiom. In applying this version of the theory, we assume a sufficiently large N so that the probability of no elements being sampled, $(1 - \theta)^N$, is essentially zero.) Because the sampling is random, there should be approximately $\theta N p_n$ conditioned elements in the sample; thus, $P(A_{1,n})$ is approximately equal to p_n, the proportion of conditioned elements in the set S. (It is implicitly assumed that the average of a ratio is the ratio of the averages, an assumption which, for large N, is approximately correct.) After sampling, S contains $(N - \theta N)$ elements. These have not changed their conditioning state, so for them the proportion of elements conditioned to the A_1 response remains p_n. The sample consists of θN elements, all of which return to S conditioned to A_1 if an E_1 event occurs. Thus, on trial $n + 1$, the set S contains $(N - \theta N)p_n + \theta N$ conditioned elements, or a proportion

$$p_{n+1} = (1 - \theta)p_n + \theta \tag{1}$$

obtained by dividing the number of conditioned elements in S by the total number of elements N. If an E_2 event had occurred, the

$N - \theta N$ elements not sampled would remain conditioned as they were before the reinforcement, but all the θN elements sampled would return conditioned to A_2; thus

$$p_{n+1} = (1 - \theta)p_n \tag{2}$$

Derivation of the fundamental learning equation Equations 1 and 2 are called *linear operators* or *linear difference equations.* They are analogous to differential equations, but they are used for discrete trials instead of continuous time. (See Goldberg, 1958, for a good exposition of difference equations.) Following Bush and Mosteller,[4] we can simplify later derivations by rewriting Equations 1 and 2 using operator notation.

$$L_1(p_n) = (1 - \theta)p_n + \theta \tag{1a}$$
$$L_2(p_n) = (1 - \theta)p_n \tag{2a}$$

The axioms presented above express the primitive terms and the axiomatic relationships of the theory. "Stimulus element" and "response" are primitive terms of the theory. They are not defined explicitly and, within the theoretical structure, they need not be. The events, E_i, have the same status as responses. The axioms are likewise empirically undefined. Elements are "connected" to responses, elements are "sampled," and the sampled elements determine the probability of a response. To establish a theory of any empirical process, we must state rules of correspondence for the primitive terms and basic axioms. Of course, the words used to describe the primitive terms help to show the kind of correspondences we expect. We can now consider the rules of correspondence for PL.

As we have stated, the signal is considered to be composed of a set of N elements. The key presses are the responses A_1 and A_2. The outcomes O_1 and O_2 seemingly reinforce responses A_1 and A_2, and thus they are designated E_1 and E_2. Sampling occurs when the signal is turned on. The sample determines the probability of the response that the subject makes. One of the outcomes occurs and acts so as to reinforce the corresponding response. Estes justifies this reinforcement rule with the contiguity assumption. The O_j outcome is assumed to produce the A_j response. Thus, the A_j response is the last response made on the trial and, by the contiguity rule, the last response made in some stimulus context becomes associated with that context. Note that some of Guthrie's (1959) notions about how reinforcement works are brought into the description at this point. They are not formally represented in the axioms, but are used to justify why elements are connected to the response associated with the outcome on the trial.

We must now say something about initial conditions. On the first trial, that is, the first time the signal is presented, we assume that the elements are in some way conditioned in order to evoke a response. Because the experimental situation is symmetrical, we assume an initial probability of .5 for either response. To eliminate any possible bias toward the left or right response, half of the subjects are run with the left response an A_1 and the right response an A_2. For the other half, the left response is an A_2 and the right response an A_1. In practice the probability on the initial trial is always close to .5.

We can now make some simple deductions from the model. Assume that, on trial 1 of a learning experiment, the initial probability is p_1. Now assume that the E_1 reinforcing event is repeated once every trial thereafter. By Equation 1a

$$\begin{aligned} p_2 &= L_1p_1 = (1 - \theta)p_1 + \theta \\ p_3 &= L_1p_2 = (1 - \theta)p_2 + \theta \\ &= (1 - \theta)^2p_1 + (1 - \theta)\theta + \theta \end{aligned}$$

and

$$\begin{aligned} p_4 = L_1p_3 = (1 - \theta)^3p_1 + (1 - \theta)^2\theta \\ + (1 - \theta)\theta + \theta \end{aligned}$$

[4]Bush and Mosteller (1955) began by assuming a very general linear operator to represent the change in probability from one trial to the next. Equations 1 and 2 are special cases of the more general approach they took. As we shall see later, it is the stimulus representation of the theory that has been more productive of new ideas and research in human learning and therefore the more general linear operators are not of major concern at this time. For a recent discussion of this approach see Sternberg (1963).

Generalizing, we can make the hypothesis that

$$p_n = (1-\theta)^{n-1}p_1 + (1-\theta)^{n-2}\theta + \cdots + (1-\theta)\theta + \theta$$

The terms to the right of the plus sign comprise a geometric series of the form

$$S_k = \sum_{i=0}^{k} ar^i = a\frac{(1-r^{k+1})}{(1-r)} \qquad (3)$$

where $a = \theta$, $k = n-2$, and $r = (1-\theta)$. The solution to this series is easily proved by noting that

$$\begin{aligned} S_k - rS_k = S_k(1-r) &= a + ar + ar^2 + ar^3 \ldots ar^k \\ &\quad - ar - ar^2 - ar^3 \ldots - ar^k - ar^{k+1} \end{aligned}$$

which equals $a - ar^{k+1}$. Thus, $S = a(1-r^{k+1})/(1-r)$. In terms of θs and $k = n-2$,

$$p_n = (1-\theta)^{n-1}p_1 + \frac{\theta[1-(1-\theta)^{n-1}]}{1-(1-\theta)} \qquad (4)$$

and after algebraic simplification

$$p_n = 1 - (1-p_1)(1-\theta)^{n-1} \qquad (5)$$

Equation 5 is correct for $n = 1$. Is it correct for $n+1$? By Equation 1, $p_{n+1} = (1-\theta)p_n + \theta$. Applying the basic difference equation to Equation 5 yields

$$\begin{aligned} p_{n+1} = (1-\theta) - (1-p_1)(1-\theta)^n \\ + \theta = 1 - (1-p_1)(1-\theta)^n \quad (6) \end{aligned}$$

which is the same as Equation 5 if n is replaced by $n+1$. Thus, by proof by induction,[5] we can show that Equation 5 is the general solution to the difference equation. By a general solution, we mean that values for any trial n are expressed in an explicit formula in which only a fixed number of constants are required—in this case, the initial probability value, p_1. A few points about Equation 6 should be noted. Remember that θ is the probability that an element will be sampled on a given trial. If $\theta = 0$, then no element will ever be sampled, $p_2 = p_1$, and no learning occurs immediately after one reinforcement. Therefore, $p_n = p_{n-1} = \ldots = p_2 = p_1$. For $\theta \neq 0$ or $\theta \neq 1$, $(1-\theta)^n$ will decrease to zero, so that at asymptote, as $n \to \infty, p_\infty = 1$. In other words, eventually the probability of an A_1 response will become 1.

[5]A proof by mathematical induction is a proof that a given general proposition $G(n)$ is true for all n. There are two steps to an inductive proof. First, $G(n)$ must be shown to be true for $n = 1$. Second, for any n, if $G(n)$ is true, it must be shown that $G(n+1)$ is also true. Thus, starting with $G(1)$, any value of $G(n)$ can be shown to be true by repeated application of the second step.

Theory applied to probability learning The first deduction from the theory is that if an outcome such as O_1, which has reinforcing event E_1 associated with it, is repeated
Figure 20.3. Tree diagram representing four trials of probability learning. Each path of the tree presents two probabilities; the probability of transitions between nodes is on the stems between these nodes. The response probability at each node is indicated by the operators at that node. Thus, at the top node on the far right, after 4 O_1 outcomes, the response probability is $L_1^4p_1$, and the probability of making the transition to that node is π^4.

indefinitely, the probability of an A_1 response will eventually become 1 on every trial. The rate at which the probability p_n approaches 1 depends directly on the value of θ. Intuitively, this result is not surprising. If the O_1 light comes on repeatedly, subjects will begin to predict it repeatedly. This much, the obvious, is expected of a theory. The not-so-obvious occurs when the theory is developed for the situation in which O_1 and O_2 outcomes are presented randomly with a probability of π for the O_1 event and $1 - \pi$ for the O_2 event. The rules of correspondence are the same in this case, but the derivation becomes somewhat more difficult.

It is important to start correctly, or later deductions will not be possible. Consider a very large number of subjects run under the PL experiment with π as the probability for outcome O_1. Figure 20.3 illustrates what happens to a group of subjects through trial 5 under the procedure described above. After the first reinforcement, the group is divided into two, with proportions π and $(1 - \pi)$. Those subjects who get an O_1 outcome have a new response probability of L_1p_1, whereas those subjects who get an O_2 have a new probability of L_2p_1. The group of subjects is broken into smaller subgroups until, by trial 5, there are 16 subgroups. Note that $L_1L_2p_1$ means that first the L_2p_1 operation is performed, and then, on the results of that operation, L_1 is applied. $L_2L_1p_1 = (1 - \theta)^2p_1 + (1 - \theta)\theta$, while $L_1L_2p_1 = (1 - \theta)^2p_1 + \theta$. The order in which the operators are applied makes a difference in the result. In such cases, the operators do not *commute*. In the tree in Figure 20.3, the order of the Ls is carefully preserved, whereas the order of the πs need not be because it is a simple product and does commute; that is, $\pi(1 - \pi) = (1 - \pi)\pi$.

Generally, at least 100 to 200 trials are run in PL experiments. At the end of 100 trials, there would be a possibility of 2^{99} subgroups. Usually, every subject is presented with a unique sequence of outcomes, and theoretically the particular path followed could be used to compute his exact probability for every trial. However, in addition to the practical problem of computing the probabilities, the θ and p_1 values are not necessarily known. Furthermore, we cannot measure a probability on a single trial: Either an A_1 or an A_2 response is made, giving us no information as to what the underlying probability really is. Therefore, to test the theory, a reasonable estimate of the probability is needed; it can be obtained by averaging across subjects. Assuming that all subjects have about the same p_1 and θ values, what is the probability of an A_1 response on trial 2 $[P(A_{1,2})]$? It is simply the average of the probability value obtained by the subjects who had an O_1 outcome and the probability value of those who had an O_2 outcome. Because there is not an equal number of subjects in both subgroups, the probabilities must be weighted by the proportion of subjects with each probability, namely, π and $(1 - \pi)$.

$$\begin{aligned} P(A_{1,2}) &= \pi L_1p_1 + (1 - \pi)L_2p_1 \\ &= (1 - \theta)p_1 + \theta\pi \end{aligned} \tag{7}$$

Carrying the process one step further to trial 3:

$$\begin{aligned} P(A_{1,3}) &= \pi^2L_1^2p_1 + \pi(1 - \pi)L_2L_1p_1 \\ &\quad + (1 - \pi)\pi L_1L_2p_1 + (1 - \pi)^2L_2^2p_1 \\ &= \pi L_1P(A_{1,2}) + (1 - \pi)L_2P(A_{1,2}) \\ &= \pi((1 - \theta)P(A_{1,2}) + \theta) + (1 - \pi) \\ &\qquad (1 - \theta)P(A_{1,2}) \\ &= (1 - \theta)P(A_{1,2}) + \theta\pi \end{aligned} \tag{8}$$

More generally, it can be shown that

$$P(A_{1,n+1}) = (1 - \theta)P(A_{1,n}) + \theta\pi \tag{9}$$

(You should demonstrate this for yourself.) We have shown here that the average response probability on any trial $n + 1$ can be expressed as a linear function of the average response probability on the preceding trial n. According to the theory, the linear operators are applied to individual probabilities, not to the average probability over subjects. However, we have just shown that applying the average operator to the average probability correctly expresses the change in the average probability. It is as if L_1 and L_2 were applied

to every branch of the tree and the resulting changes in the individual probabilities averaged. The fact that the average operator correctly computes probability changes is important, for it allows us to make a statement about the average probability for the process. It also permits a statement to be made about observable results or $P(A_{1,n})$, the average probability of a large number of subjects. If only 20 subjects were run, all branches could not be followed out beyond trial 4, but there is still no reason for any one branch to be chosen over any other branch and the expected value of $P(A_{1,n})$ as computed from the average operator is the value we would expect on the average. Of course, with a small number of subjects, deviations from this average can be expected, depending on the branches selected. Predictions are not exact but probabilistic.

The successive application of the recursive Equation 9 in a manner similar to that used in the development of Equation 5 yields a result very similar to that of Equation 5.

$$P(A_{1,n}) = \pi - [\pi - P(A_{1,1})](1 - \theta)^{n-1} \quad (10)$$

with π replacing 1. The π occurs because L_1 and L_2 are applied randomly, and the probability of an A_1 response cannot continue to increase to the value 1. Instead it tends to level off at π as an asymptote. Because π is the probability of reinforcing with the outcome O_1, the probability-matching law results.

Parameter estimation There should be, ideally, an addition to the theory stating how to compute the θ value because, without it, exact predictions cannot be made. The mechanism for such an estimate is present (the average proportion of elements sampled on each trial), but, as was observed earlier, one of the characteristics of the theory is its lack of specificity about the nature of elements. The lack of specificity was considered an advantage because, at this point in theory construction, there is little evidence to guide the experimenter in tying elements to physical aspects of the environment. (Later, we shall see that such assignments may be very difficult indeed.) The purpose of the theory is to predict the form of the learning curve and to see if the data conform to the prediction. Therefore, a θ value that will give the best fit of data and theory is sufficient at this time. There are two parameters, $P(A_{1,1})$ and θ. The $P(A_{1,1})$ value is usually evaluated a priori on rational grounds; that is, because of symmetry and counterbalancing, $P(A_{1,1}) = .5$. To estimate θ, some statistic of the data is equated with its theoretical expression and the resulting equation solved for θ, a procedure known as an estimation by the method of moments. One straightforward and simple technique is to equate the total number of A_1 responses observed over N trials to the theoretical expression for that number. If the learning curve (Equation 10) were continuous, the total area under it could be determined by integration and a θ value selected that would yield the same area. However, Equation 10 is discrete rather than continuous; therefore, summing, the operation analogous to integration, is used. In this case, the sum of Equation 10 for N trials is

$$\begin{aligned} P_1^{(N)} &= \sum_{n=1}^{N} P(A_{1,n}) \\ &= \sum_{n=1}^{N} [\pi - (\pi - P(A_{1,1}))(1 - \theta)^{n-1}] \\ &= N\pi - (\pi - P(A_{1,1})) \sum_{n=1}^{N} (1 - \theta)^{n-1} \quad (11) \end{aligned}$$

The last summation term is evaluated as before (Equation 3), yielding

$$P_1^{(N)} = N\pi - (\pi - P(A_{1,1}))\frac{(1 - (1 - \theta)^N)}{\theta} \quad (11a)$$

If N is sufficiently large and if $(1 - \theta)$ is sufficiently smaller than 1, $(1 - \theta)^N$ will be near enough zero to ignore. In that case, the estimate for θ is found by taking the observed value of $P_1^{(N)}$, call it $\hat{P}_1^{(N)}$, and solving Equation 11 for θ. The solution is

$$\hat{\theta} \approx \frac{[\pi - P(A_{1,1})]}{N\pi - P_1^{(N)}} \tag{12}$$

where $\hat{\theta}$ represents the estimate of θ.

Average learning curve by blocks If an experiment is run for 250 trials, 250 probabilities would have to be predicted and plotted using Equation 10. However, there are two problems with using Equation 10 as it is: One is the tedium of computing and plotting so many points. The second is the lack of stability of each data point if, for example, only 20 subjects were run. Obviously, the way to handle the problem is to average over trials and plot response proportions for a block of K trials. The expected number of A_1 responses in N trials was stated in Equation 11a. By substituting K for N, we obtain the expected number of A_1 responses in the first K trials. Likewise, if in Equation 11, the sum went from $n = K + 1$ to $2K$, we would obtain the expected number of A_1 responses in the second block of K trials. In general, if $n = (m - 1)K + 1$ to mK, we would obtain the expected number of A_1 responses in the mth block. If we divide the number of A_1 responses in a block by the number of trials in the block, we obtain the expected proportion of A_1 responses in the block. Thus, the proportion of A_1 responses in the mth block of K trials is

$$P_m^{(K)} = \pi - \frac{[\pi - P(A_{1,1})]}{K} \frac{[1 - (1 - \theta)^K]}{\theta} (1 - \theta)^{K(m-1)}$$
$$= \pi - C(1 - \theta)^{K(m-1)} \tag{13}$$

where

$$C = \frac{[\pi - P(A_{1,1})]}{K} \frac{[1 - (1 - \theta)^K]}{\theta}$$

Averaging of Data

Psychological data, like all biological data, are characterized by a great deal of noise. The experimenter tries to reduce variation between measures of the dependent variable by controlling as many factors as possible. However, even in the best of situations, the experimenter is often left with a dependent variable that is noisy. When faced with variable response measures, the experimenter can average scores and treat means instead of individual cases.

Two important points about averaging should be made at this time. The first is related to theory construction. Earlier theoretical approaches to learning in psychology, particularly that of Hull, assumed a deterministic process. The fact that deterministically predicted outcomes rarely occurred was handled by assuming that each determined response was influenced by a distortion process of a random nature. Usually, the experimenter superimposed a normal curve upon the response, if not explicitly as Hull did, at least implicitly by assuming that, when an average was taken, the effect of random influencing factors would average out. In SLT a different approach is taken. We assume from the initial axioms of the theory that variation in responses is to be expected. This variation results from the sampling of stimulus conditions, from the fact that the sample determines only the probability of a response (that is, the probability of a response is determined by the ratio of conditioned to unconditioned elements), and from the fact that the response changes due to reinforcement also change probabilistically. In SLT, variation in behavior is axiomatic, not the result of poor control or of factors of no concern to the theorist. However, if the stimulus were completely controlled, so that the particular elements presented could be designated, the response would become more determined, and perhaps even completely determined. In other words, the theorist admits that complete control of the stimulus is impossible because the subject participates in determining what it is by his very attention to it and because any environment is likely to change somewhat from trial to trial and from organism to organism. Thus, SLT is referred to as a stochastic theory as opposed to a deterministic one.

The second point has to do with when it is proper and when it is not proper to average data. The scientist is basically interested in the on-going process. When the dependent variable is noisy, he can usually get some idea of the process by averaging data. Now in PL, almost all experimental results have been based on average data. Nearly every paradigm to be discussed in this chapter depends on average data. The same is true for the bulk of research on problems of learning, even including the operant work in which cumulative curves are presented for individual subjects. However, averaging may conceal or distort the fact that various processes are going on in different subjects. In other words, it is not proper to infer that the average reflects the behavior of the individual subject (see, for example, Skinner, 1938; Sidman, 1952). How then is the psychologist to discover basic learning processes when confronted with noisy data? The solution is analogous to testing a theory. The average curve is derived as a logical consequence of the hypothetical individual curves. Those who argue that it is never appropriate to average do not regard the average curve as a deduction but as an induction. However, the scientific process is somewhat more complicated than empirical laws dictated by overwhelming data. Furthermore, a finite collection of data can usually be accounted for by a number of theories (Kemeny, 1959). The solution is a dynamic process between induction and deduction. The data are used to evaluate a hypothesis. If the data are not compatible with the hypothesis, then another hypothesis is considered that retains all the correct predictions of the previous hypothesis but also predicts the new set of data correctly. (See Platt, 1964.) In a similar way, the average curve does not necessarily give information about the underlying process, but rather it is or is not compatible with hypothesized underlying processes.

Estes (1956) has treated this problem in a very exact and complete manner. He designates three types of function. In the first type, the average curve is similar in form to the individual curves and has parameter values that are the average of the parameters of the individual curves. An obvious example would be a simple linear equation of the form $y = a + bx$. In this case, of course, no problems arise in averaging over subjects. In the second class of curves, the form remains the same, but the parameters of the average curve are not the average of the parameters of the individual curves. Estes gives the example $y = \log (bx)$. In this case, averaging will not distort the form of the results, but no inference can be made about the individual parameter values. In the third class of curves, both the form and parameters are changed by averaging. An example is the typical growth function illustrated by Equation 10. In Equation 10, notice first that, because π is only an added constant, as is a in the linear equations, it is not affected by averaging. Regardless of parameter values, the asymptote of π is predicted. However, the rest of the equation involves averaging exponentials, a process that distorts the form of the curve to some degree if the parameters are very variable.
Figure 20.4. Contrast between (1) the average of two exponential curves and (2) the exponential curve fitted with the parameter estimated from the average data.

Two curves are presented in Figure 20.4. The average curve results from averaging the expected curve from two subjects with different learning rates: $\theta = .1$ and $\theta = .4$. The second curve is the best-fitting exponential of the type presented in Equation 10. The effect of variation in the θ parameter value can be seen in the fit obtained. Extreme θ values do not distort the fit a great deal and the distortion is such that the theoretical exponential is too low in the beginning and too high near the end. In general, such a discrepancy in fitting a learning curve results from heterogeneity of learning parameters. If there is not much variability in the θ values, it is not a serious problem. One additional point must be made: If individual parameters are estimated, individual curves should be generated and averaged. This average curve should agree with the average curve of the original data. Individual parameters should not be averaged to obtain the average parameters for the best-fitting group curve.

Basic Facts about PL

Thus far, the discussion of PL has been somewhat abstract. We can now apply some of the ideas to see just what is and what is not known about PL. Investigators have been interested in three important statistics: (1) the learning curves and asymptotic behavior, (2) recency analyses, and (3) sequential statistics.

Learning curves and asymptotic behavior We have already presented the theoretical work for the learning curve. Edwards (1956) and more recently Luce and Suppes (1965) have summarized the studies in simple noncontingent PL with respect to the asymptotes observed. An examination of some 16 experiments by almost as many experimenters, involving a complete range of π values and over 685 subjects, has led Luce and Suppes to conclude that "with the exception of Edwards' (1961) 1000-trial study, the experiments without payoff appear to confirm the probability-matching hypothesis, at least for group averages" (Luce & Suppes, 1965, p. 393). Now, of the 39 groups that Luce and Suppes considered, 8 did not seem to be at asymptote, and 19 of the groups were over the π values (or under for πs less than .5). The number of trials seems to be crucial here—longer experiments tend to show overshooting. For example, Myers, Fort, Katz, and Suydam (1963) and Edwards (1961) ran 400 and 1000 trials, respectively, and all their groups showed overshooting.

Figure 20.5. Learning curves from two probability learning experiments.

Figure 20.5 presents two learning curves from two different studies. The six-block curve is from the Friedman et al. study (1964), in which 288 trials were run after a series of 17 48-trial blocks with changing π values. The 288 trials began on the third day of testing after 48 trials with $\pi = .5$. The 80 subjects in the Friedman et al. study had a great deal of heterogeneous previous experience. The Reber and Millward data (1968) consisted of 1000 trials of $\pi = .8$, with four sequences and 15 subjects. Both curves are representative of results of other experiments. When overshooting occurs, it is, for example, around .85 for $\pi = .8$. The Reber and Millward asymptote seems to stabilize at the new level.

Various explanations for the overshooting discussed above have been suggested. Perhaps the most obvious one is that a few subjects tend to "maximize"; that is, they always

TABLE 20.1 RUNS ANALYSIS STATISTICS

predict the more frequent event. Although such a hypothesis seems straightforward, it is not a simple one to test because we need to know the expected distribution of A_1 proportions within a block of trials. For the linear model, this distribution is not known (Estes & Suppes, 1959). Remember that every subject is not expected to match π exactly; the event sequence and the size of θ tend to cause subjects to spread around the π asymptote. Researchers often look at their protocols and find a subject who seems to be systematically behaving in a way not in accord with the theory. However, in his 1964b study, Estes compared "stat"[6] subjects with real subjects and found that stat subjects, run exactly as the theory requires, also show such aberrant protocols. Although there has been no definitive study, the evidence seems to point to a small shift involving almost all subjects, rather than a large shift involving only a few subjects. To demonstrate otherwise, statistics would have to be derived showing individual protocols that deviate systematically from the prediction.

In general, there is little question about the adequacy of the negatively accelerated learning curve before asymptote. Deviations, when they occur, can usually be accounted for by the heterogeneity of the learning rate or by the results of subjects systematically "tracking" the varying sequence of events. In most studies, only a few sequences have been used for the 15 to 25 subjects in a group. If a particular sequence happens by chance to fluctuate widely, this produces a similar fluctuation in the response probabilities. Tracking behavior is, of course, predicted by SLT; the neatness of the tracking behavior can be seen in the Friedman et al. study (1964).

Recency analyses Gamblers are believed to be sustained in their gambling behavior by

[6] A stat subject is a subject-protocol generated by numeric means which corresponds exactly to some theory (Bush & Mosteller, 1955).

the fallacious belief that the longer their string of losses, the more likely they are to win on the next gamble. This is a fallacy because each gamble should be considered an independent event with the same constant probability of a win or a loss, regardless of the number of previous wins or losses. Jarvik (1951) observed that, in the PL routine, subjects predicted the O_2 outcome with a very high probability after a long string of O_1 outcomes had taken place. He labeled such behavior the *gambler's fallacy*. More technically, the analysis of the effects of outcome runs on prediction probabilities is called *recency analysis*. Consider a subject on trial n with a response probability $P(A_{1,n})$. Now present the subject with $k\,O_1$ outcomes in a row, starting on trial n. His new probability on trial $n+k$, $P(A_{1,n+k}) = 1 - (1 - P(A_{1,n}))(1-\theta)^{k-1}$ (see Equation 6). Obviously, this is a monotonically increasing function with an asymptote of 1, yet Jarvik (1951), Nicks (1959), Edwards (1961), and many others have observed a nonmonotonic function. Usually, after from one to three outcomes, the empirical curves begin to decrease. Such a result is called a negative-recency effect, meaning that recent events are acting as negative reinforcers.

Table 20.1 presents 20 trials of events and responses. The probabilities $P(A_{1,n+k+1} | E_{i,n+k}, E_{i,n+k-1}, \ldots, E_{i,n+1}, E_{j,n})$ for $k = 0, 1, 2, \ldots,$ stand for the $P(A_{1,n+k+1} |$ a run of E_i events of length k). Although it is not necessary, it is customary to begin the run on trial n with an E_j event (different from E_i). There are two values of both i and j, but because only the cases where $i \neq j$ are of interest, there are only two recency curves: $P(A_{1,n+k+1} | E_{1,n+k} \ldots E_{2,n})$ and $P(A_{1,n+k+1} | E_{2,n+k} \ldots E_{1,n})$.

To begin the analysis, let $k = 0$. First count the number of times an E_j event occurs on trials 1 through 19. There are 10 such trials for $j = 2$. Then, for just those trials (2, 6, 7, 9, . . .), count the number of times that an A_1 response is made on the very next trial (3, 7, 8, 10, . . .). There are 6 A_1 responses following E_2 events. The ratio of the A_1 responses to the E_j events determines $P(A_{1,n+1} | E_{j,n})$. In the example, $P(A_{1,n+1} | E_{2,n}) = 6/10 = .60$. If $k = 1$, count the number of pairs of trials, n and $n+1$, that contain $E_{j,n}E_{i,n+1}$. Table 20.1 shows four trials for $j = 2$ and $i = 1$: 2 and 3, 7 and 8, 9 and 10, and 15 and 16. Now count the A_1 responses on trials 4, 9, 11, and 17. In our example, there are two A_1 responses and $P(A_{1,n+2} | E_{1,n+1}E_{2,n}) = .50$. Continue the procedure for as many k values as are statistically reasonable. Usually, of course, more than one response and event sequence are involved. In such cases, the total number of A_1 responses summed over subjects and trials is divided by the total number of event patterns meeting the criteria defining the run. Although analyses of runs are tedious to calculate by hand, computers can easily be used to calculate hundreds of trials for large numbers of subjects. Because the sequence begins with the event opposite from the one involved in the run itself, the theoretical equation for these statistics is slightly different from Equation 6. Because each run of an E_1 event begins on trial n with an E_2 event, $P(A_{1,n})$ is first operated on by L_2:

$$L_2P(A_{1,n}) = (1-\theta)P(A_{1,n})$$

The L_1 operator is then applied successively for k E_1 events, yielding

$$(1-\theta)^{k+1}P(A_{1,n}) + \theta[(1-\theta)^{k-1} + (1-\theta)^{k-2} \cdots (1-\theta) + 1]$$

which leads to the solution

$$P(A_{1,n+k+1} | E_{1,n+k} \ldots E_{2,n}) = 1 - (1-\theta)^k[1 - (1-\theta)P(A_{1,n})] \quad (14)$$

Likewise, if E_2 runs are considered,

$$P(A_{1,n+k+1} | E_{2,n+k} \ldots E_{1,n}) = (1-\theta)^k[P(A_{1,n})(1-\theta) + \theta] \quad (15)$$

Sequential statistics are usually computed after response proportions have reached an asymptote; in this case, as $n \to \infty$, $P(A_{1,n}) \to \pi$. Notice that both functions are monotonic, one increasing to 1 and the other decreasing to 0. They begin slightly below and above $P(A_{1,n})$, respectively, because of the opposite event that initiates the run.

TABLE 20.2 RECENCY CURVES FROM THE EXPERIMENTS BY FRIEDMAN ET AL. AND REBER AND MILLWARD

$P(A_{1,n+k+1} \mid E_{i,n+k}, E_{i,n+k-1}, \ldots, E_{i,n+1}, E_{j,n}), \quad i \neq j$

Reber and Millward	2	.85	.75	.77	.33	—					

The recency prediction by SLT has provoked a great deal of discussion. Jarvik (1951) was the first to report negative recency effects. Since his report was made, most PL experiments have shown a negative recency effect. However, few experiments have run more than 300 to 400 trials, and many of these have randomized in such a way as to insure $N\pi$ O_1 outcomes within each trial block of size N. Sellecting events in a trial block of some restricted size, such as 25 or 50, restricts the length of the runs that can be made by chance in the sequence. A study by Jones and Myers (1966) demonstrated that this restriction is crucial in the recency analysis. Jones and Myers randomized the events in blocks of 20 and 300 trials. The distributions of the length of the runs of the events were very different: Runs longer than 4 or 5 were rarely generated in the short blocks, but they were rather frequent in the longer block. Jones and Myers found that the responses that subjects made after being tested with runs of different lengths reflected the relative probabilities of the lengths of the runs themselves. An earlier study by Derks (1963) had reported a very similar result. In another study (1962), Derks plotted recency curves as a function of trials. The curves for the first 250 trials showed large negative recency, but were nearly flat by the trial block 751–1000. The change over trials in the recency function was noted by Edwards (1961). Lindman and Edwards (1961) performed a follow-up study to compare the results reported by Edwards with those of Nicks (1959), who had observed large negative recency effects. Lindman and Edwards confirmed that on early trials there is negative recency, which begins to diminish after only 100 trials. Witte (1964) built in negative recency effects by presenting event sequences with alternation tendencies much larger than is found in simple Bernoulli trials. The subjects were given 300 trials under these conditions and then 1200 regular Bernoulli trials. By the end of the 1200 trials, the subjects were showing positive recency. Finally, Gambino and Myers (1966) have shown that the degree of negative recency depends on the variance of the runs as well as their average length: More variability leads to less negative recency. They suggest that the function of increased average run length is to increase run-length variability.

An illustration of typical recency curves after a large number of trials is shown in Table 20.2, which presents the recency data from two different experiments. The data from Friedman et al. represent the last 96 trials of a $\pi = .8$ sequence of 288 trials that followed 864 trials with a variety of π values changed every 48 trials. The data of Reber and Millward plot the runs analysis from the second block of 500 trials of a simple probability-learning experiment with $\pi = .8$. The Friedman et al. curve, involving $P(A_1 \mid E_1)$ runs, rises at first, showing good positive recency, but it becomes too flat after $k = 4$. The Reber and Millward curve is remarkably unchanging. However, note that the curves of the

$P(A_1|E_2)$ runs in both experiments show large changes.

Sequential statistics By a *sequential statistic,* we mean the response probabilities following any pattern of events and/or responses. The runs analysis, a special kind of sequential statistic, is the probability of a given response following a run of events. Other patterns include alternations of events and runs of responses. Derivations of a number of these special statistics can be found in Bush and Mosteller (1955), Estes and Suppes (1959), and Atkinson and Estes (1963). Anderson's article (1959) on the procedures for deriving such statistics is especially good.

We consider only two special statistics at this time. The first is the alternating-event sequence. Anderson (1960, 1964) has calculated a number of special sequential statistics of the form $P(A_{i,n+k+1}|E_{j,n+k}, E_{k,n+k-1}, \ldots, E_{m,n})$. By a judicious choice of pairs of these statistics, he found a set of pairs with the same theoretical value according to statistical learning theory. However, in a study he ran with $\pi = .5$ for 500 trials, the observed values for the set of pairs were not equal. The discrepancies he found suggest that there are response patterns in the data other than negative recency and alternation tendencies. For example, one pattern difference considered was $E_{1,n+3}E_{2,n+2}E_{2,n+1}E_{1,n} - E_{2,n+3}E_{2,n+2}E_{2,n+1}E_{1,n}$, which had an expectation of $\theta(1-\theta)^3$. The expected value was .1, but a value of 0 was observed. This seems to show that the E_1 event on the immediately preceding trial has no effect on the response probability on trial $n + 4$.

The second sequential statistic involves the event and response on the previous trial. This statistic is important because it relates to whether being right is more or less reinforcing than being wrong. In other words, does an E_1 reinforcement increase the A_1 response probability more if it occurs on an A_1 response trial than on an A_2 response trial? Consider the following two expressions:

$$P(A_{1,n+1}|E_{1,n}A_{1,n}) - P(A_{1,n+1}|A_{1,n}) \qquad (16)$$

and

$$P(A_{1,n+1}|E_{1,n}A_{2,n}) - P(A_{1,n+1}|A_{2,n}) \qquad (17)$$

According to SLT, there is no difference between Equations 16 and 17. The $P(A_{1,n+1}|A_{i,n})$ terms are subtracted to adjust for the difference in the expected response probability on trial $n + 1$ because the response on the previous trial is now known. Knowledge of the response on trial n provides information about the probability of the response on trial $n + 1$ because the A_1 response on trial n selects unequally those subjects with a higher A_1 response probability on trial n. Estes' analysis (1964b) shows that most learning seems to occur on correction trials, that is, those on which an error is made and the subject must make a correction response. Estes' analysis is supported by the fact that another model, the pattern model, which allows response-probability changes only on error trials (Atkinson & Estes, 1963), fits a little better than SLT. Estes shows that, with large θ values and large $P(A_1)$ values, SLT predicts that the largest probability changes are on error trials. These conclusions can be interpreted as support for a contiguity theory of learning as opposed to a drive-reduction theory. Such use of sequential statistics to analyze results, so that a clear statement concerning issues can be made, represents an important development in the psychology of learning.

The derivation of sequential statistics is not simple, and a proper development of the probability sample space of the model is needed to make the derivations correctly. The reader is referred to Anderson (1959), Estes and Suppes (1959), and Atkinson, Bower, and Crothers (1965) for detailed treatments of the derivation of sequential statistics.

To illustrate some of the pitfalls in deriving sequential statistics as well as to explicate Equations 16 and 17, these equations will be derived. First, note that $P(A_{1,n+1}|A_{i,n})$ does not equal $P(A_{1,n+1})$. The lack of equality is due to the fact that the subjects have different response probabilities. Those subjects with a high probability of making an A_1 response are

more likely to make that response on trial n and on trial $n + 1$. Thus, when considering only those subjects who make an A_1 on trial n, we automatically select those subjects with a higher probability of making an A_1 response. This selection also occurs in the analysis of the sequential statistics $P(A_{1,n+1} | E_{i,n}, A_{k,n})$. Thus, if we look only at $P(A_{1,n+1} | E_{1,n}, A_{1,n})$ and $P(A_{1,n+1} | E_{1,n}, A_{2,n})$, we cannot answer the question of whether presenting an E_1 on trials when a subject makes an A_1 response is more or less reinforcing than presenting an E_1 on trials when a subject makes an A_2 response.

Perhaps the simplest way to illustrate these statistics without extensive formal development is to consider only the first three trials. If all subjects start with p_1 as the initial probability of an A_1 response, by trial 3 they branch into four different probabilities. Figure 20.3 presents the tree of response probabilities and the probabilities of the paths taken by each subject. On trial 2, there are two subsets of subjects. The first has the response probability $L_1p_1 = (1 - \theta)p_1 + \theta$ and the second $L_2p_1 = (1 - \theta)p_1$. Let us call these two probabilities $p_{1,2}$ and $p_{2,2}$, respectively. The probabilities of taking the two different paths (or in a real experiment, the proportion of subjects who will follow each path) are π and $1 - \pi$. Now consider $P(A_{1,3} | A_{1,2})$.

$$P(A_{1,3} | A_{1,2}) = P(A_{1,3}, A_{1,2}) / P(A_{1,2})$$

where

$$\begin{aligned} P(A_{1,3}, A_{1,2}) &= \pi p_{1,2}[\pi L_1 p_{1,2} + (1 - \pi) L_2 p_{1,2}] \\ &\quad + (1 - \pi) p_{2,2}[\pi L_1 p_{2,2} + (1 - \pi) L_2 p_{2,2}] \qquad (18) \\ &= \pi p_{1,2}[(1 - \theta) p_{1,2} + \theta\pi] \\ &\quad + (1 - \pi) p_{2,2}[(1 - \theta) p_{2,2} + \theta\pi)]. \end{aligned}$$

Now,

$$P(A_{1,2}) = \pi p_{1,2} + (1 - \pi) p_{2,2} \qquad (19)$$

is called "the first raw moment of the response distribution." A similar statistic, the second raw moment, is defined as

$$P(A_{1,2}^2) = \pi p_{1,2}^2 + (1 - \pi) p_{2,2}^2 \qquad (20)$$

In terms of these quantities,

$$\begin{aligned} P(A_{1,3}, A_{1,2}) \\ = (1 - \theta) P(A_{1,2}^2) + \theta\pi P(A_{1,2}) \qquad (18a) \end{aligned}$$

If we divide Equation 18a by the first moment, $P(A_{1,2})$, we obtain the conditional probability

$$P(A_{1,3} | A_{1,2}) = \frac{(1 - \theta) P(A_{1,2}^2)}{P(A_{1,2})} + \theta\pi \qquad (21)$$

Note that $P(A_{1,2}^2) \neq P(A_{1,2}) \cdot P(A_{1,2})$. The second raw moment is the weighted sum of the square of the individual probabilities, not the square of the weighted sum of the individual probabilities. Proceeding in an exactly analogous way, the following statistic is derived.

$$\begin{aligned} P(A_{1,3} | A_{2,2}) \\ = (1 - \theta) \frac{P(A_{1,2}) - P(A_{1,2}^2)}{1 - P(A_{1,2})} + \theta\pi \qquad (22) \end{aligned}$$

Similarly, but restricting the transitions considered to those appropriate to applying an E_i event, the two conditional probabilities involving the event on the preceding trials are derived.

$$\begin{aligned} P(A_{1,3} | E_{1,2}, A_{1,2}) \\ = (1 - \theta) \frac{P(A_{1,2}^2)}{P(A_{1,2})} + \theta \qquad (23) \end{aligned}$$

$$\begin{aligned} P(A_{1,3} | E_{1,2}, A_{2,2}) \\ = (1 - \theta) \frac{P(A_{1,2}) - P(A_{1,2}^2)}{1 - P(A_{1,2})} + \theta \qquad (24) \end{aligned}$$

Now, to correct for the bias due to the response made on trial 2, we subtract Equation 21 from 23, and Equation 22 from 24 and, in both cases, obtain $\theta(1 - \pi)$ as the expected effect of an E_1 event. According to SLT, the response made on the previous trial is irrelevant to the change in response probability. Estes (1964b) reports results for this test and cannot find significant differences between Equation 23 minus Equation 21 on the one hand and Equation 24 minus Equation 22 on the other, indicating that in fact the reinforcing effect of the event is independent of the response made.

Further Developments of SLT: Stimulus Variables

There are various ways to extend theories. One is to try different versions of the basic axioms and determine the implications for the various axioms tried. These implications can then be related to psychological processes to see if they are or are not reasonable. Another way to extend theories is to attempt to apply them to new or modified experimental situations. An experimental routine is a complex procedure involving many arbitrarily determined parameters. The trial times, the stimuli used, the response the subject makes, and so on, are arrived at through trial and error in the laboratory. The experimenter is constantly thinking of variations in his procedure, many of which seem important psychologically because they test a different aspect of the process under investigation. These two methods of extending theories are rarely independent but usually go on simultaneously. In the material that follows, both extension of theory and variation in experimental procedure are discussed.

In the section on theoretical development, the basic concepts of statistical learning theory are presented. In this section we expand the basic idea of representing the stimulus environment by a set of elements (Estes & Burke, 1953; Burke & Estes, 1957). The treatment of discrimination, stimulus-compounding, generalization, stimulus fluctuation, and other experimental procedures that require manipulation of the stimulus conditions are qualitatively handled fairly adequately by the extensions of SLT to be discussed. Experimental facts established since these ideas were formulated have uncovered shortcomings in most of them, but because so much of the later theoretical elaboration depends on these early formulations, they are worth reviewing briefly now.

Figure 20.6. Paradigms of classical and probabilistic discrimination procedures. S signifies the beginning of the trial. T_i is the type of trial presented. Trial type T_i is presented with probability β, and π_{ij} is the probability that outcome O_j will follow trial type T_i.

Discrimination A discrimination procedure consists of a series of trials containing various stimuli, some of which are to be responded to in one way and others in a different way. Figure 20.6 presents a paradigmatic representation of the simple two-stimulus classical discrimination situation. (The term *classical* denotes a perfect correlation between outcome O_1 and stimulus T_1 and between outcome O_2 and stimulus T_2.) β represents the probability or proportion of the times that stimulus T_1 is presented. Typically, T_1 and T_2 are presented randomly and equally often.

The SLT analysis of classical discrimination learning is quite straightforward. First, we represent each stimulus T_i by a set of stimulus elements S_i. Now if we wish to represent anything other than two simultaneous acquisition

processes, the two sets of stimuli must have some elements in common. These common elements constitute a set designated S_C^* and equal to the intersection of the set S_1 and S_2, that is, $S_C^* = S_1 \cap S_2$. The set S_C^* reflects the degree of similarity between the two stimuli. The number of elements in the intersection is designated N_C. With N_C elements common to S_1 and S_2, there are only $N_1^* = N_1 - N_C$ elements in S_1^* that are unique to the T_1 stimulus. Similarly, $N_2^* = N_2 - N_C$ elements in S_2^* are unique to T_2. The presence of common stimulation is critical in determining both the rate of learning the discrimination and the asymptotic performance. Consider the learning function for the elements in S_1^*, which are consistently reinforced on a proportion β of the trials and are not changed on a proportion $1 - \beta$ of the trials. Let $p_{i,n}^*$ represent the proportion of elements in set S_i^* conditioned on trial n. Then $p_{1,n+1}^* = (1 - \theta_1)p_{1,n}^* + \theta_1$ with a probability β and $p_{1,n+1}^* = p_{1,n}^*$ with a probability $1 - \beta$. On the average, the change on each trial will be

$$p_{1,n+1}^* = (1 - \theta_1\beta)p_{1,n}^* + \theta_1\beta \qquad (25)$$

The general solution is

$$p_{1,n}^* = 1 - (1 - p_{1,1}^*)(1 - \theta_1\beta)^{n-1} \qquad (26)$$

This function has an asymptote of 1, so all the elements in S_1^* become conditioned to the A_1 response. Similarly,

$$p_{2,n}^* = p_{2,1}^*[1 - \theta_2(1 - \beta)]^{n-1} \qquad (27)$$

and all the elements in S_2^* are conditioned not to A_1 but to A_2. Note the relationship between Equation 5 and these equations.

In each of these functions, the rate of learning is a function of the β parameter—as intuitively it should be, for, if a stimulus is presented only on a small proportion of the trials, we would expect learning to occur proportionally more slowly. Now consider the elements in S_C^*. They are sampled on every trial, but when they are sampled with S_1^*, they become conditioned to A_1, whereas when they are sampled with S_2^*, they become conditioned to A_2. The derivation for this situation is exactly the same as that for the probability-learning situation (Equations 9 and 10), but with β replacing π. Thus, the learning curve for these elements becomes

$$p_{C,n}^* = \beta - (\beta - p_{C,1}^*)(1 - \theta_C)^{n-1} \qquad (28)$$

The dependent variables in a discrimination situation are $P(A_{1,n} \mid T_{1,n})$ and $P(A_{1,n} \mid T_{2,n})$. These variables reflect the response proportions to the two stimuli. When stimulus T_1 is presented, $N_1\theta_1$ elements are sampled on the average from S_1^*, and $N_C\theta_C$ elements are sampled from S_C^*. Likewise, on T_2 trials, $N_2\theta_2$ elements are sampled from S_2^*, and $N_C\theta_C$ elements are sampled from S_C^*. Of the $N_1\theta_1$ elements sampled from S_1^* on trial n, P_1^*,n are conditioned to A_1. Also, $p_{C,n}^*$ of the $N_C\theta_C$ elements sampled from S_C^* are conditioned to A_1. Then,

$$P(A_{1,n} \mid T_{1,n}) = \frac{p_{1,n}^* N_1\theta_1 + p_{C,n}^* N_C\theta_C}{N_1\theta_1 + N_C\theta_C} \qquad (29)$$

and similarly,

$$P(A_{1,n} \mid T_{2,n}) = \frac{p_{2,n}^* N_2\theta_2 + p_{C,n}^* N_C\theta_C}{N_2\theta_2 + N_C\theta_C} \qquad (30)$$

Asymptotically, $p_{1,n}^* = 1$, $p_{2,n}^* = 0$, and $p_{C,n}^* = \beta$, so asymptotically,

$$P(A_{1,\infty} \mid T_{1,\infty}) = \frac{N_1\theta_1 + \beta N_C\theta_C}{N_1\theta_1 + N_C\theta_C} \qquad (31)$$

and

$$P(A_{1,\infty} \mid T_{2,\infty}) = \frac{\beta N_C\theta_C}{N_2\theta_2 + N_C\theta_C} \qquad (32)$$

If there are no common elements sampled, that is, if $N_C = 0$ and/or $\theta_C = 0$, perfect discrimination occurs.

Let $W_i = N_C\theta_C/(N_i\theta_i + N_C\theta_C)$. Then the functions become

$$P(A_{1,n} \mid T_{1,n}) = (1 - W_1)p_{1,n}^* + W_1 p_{C,n}^* \qquad (33)$$

$$P(A_{1,n} \mid T_{2,n}) = (1 - W_2)p_{2,n}^* + W_2 p_{C,n}^* \qquad (34)$$

and asymptotically,

$$P(A_{1,\infty} \mid T_{1,\infty}) = 1 - W_1(1 - \beta) \qquad (35)$$

and

$$P(A_{1,\infty} \mid T_{2,\infty}) = W_2\beta \qquad (36)$$

The learning rate and asymptotes are functions of β and of the relative weights of the sample sizes from the sets S_1^* and S_2^* to S_1 and S_2, respectively. Note that, although there are parameters N_i and θ_i for $i = C$, 1, and 2, only two parameters, W_1 and W_2, are needed to represent these six parameters. In this learning process, the asymptotes are determined by three parameters and the learning functions by five. One parameter of each set, β, is determined by the experimenter. In applications of discrimination problems, certain assumptions usually can be made about the stimuli that can further reduce the number of parameters. For example, an argument of symmetry usually allows $W_1 = W_2$ to be assumed.

From the point of view of the theory, the most important finding of this derivation is that, if the two discriminative stimuli overlap at all, perfect discrimination cannot be obtained. The simple notion that discrimination consists of two simultaneous acquisition functions will not handle the results of most discrimination experiments. Somehow subjects learn to ignore the common stimulation in most discrimination situations.

A natural extension of classical discrimination is probabilistic discrimination. Figure 20.6 presents the paradigm of such a procedure. Instead of always reinforcing T_i with O_i, the reinforcement is probabilistic; that is, $P(O_j \mid T_i) = \pi_{ij}$. Another way to think about probabilistic discrimination is to assume a single set of elements partitioned into subsets. Each subset has one probability of being sampled on O_1 trials and a different probability on O_2 trials. The derivation for classical discrimination is repeated for probabilistic discrimination with one difference: The $p_{i,n}^*$ functions must include the π_{ij} probabilities of O_j reinforcement (see Equations 9 and 10). They become

$$p_{1,n}^* = \pi_{11} - (\pi_{11} - p_{1,1}^*)\ (1 - \theta\beta)^{n-1} \qquad (37)$$

and

$$p_{2,n}^* = \pi_{21} - (\pi_{21} - p_{1,1}^*)\ [1 - \theta(1 - \beta)]^{n-1} \qquad (38)$$

S_C is reinforced with E_1 on a proportion $\beta\pi_{11} + (1 - \beta)\pi_{21} = \pi_C$ of the trials.

$$p_{C,n}^* = \pi_C - (\pi_C - p_{C,1}^*)\ (1 - \theta)^{n-1} \qquad (39)$$

Popper and Atkinson (1958) made one of the first studies to test the predictions of SLT for probabilistic discrimination. They used nonsense syllables MEF and ZIL as the T_1 and T_2 stimuli with a constant $\beta = .50$ and $\pi_{11} = .85$ with π_{21} varying across groups. The results were inconsistent with predictions of the theory in that, for $\pi_{21} = .85$, .70, and .50, the estimate of $W_1 = W_2 = W$ was 0, but for $\pi_{21} = .30$ and .15, the curves could not be fit by $W = 0$. Groups run on these last two π_{21} values were not at asymptote; perhaps if they had been run longer, W would also have equaled zero. However, such a result is still inconsistent with the theory, which predicts not only that the asymptote will depend on W but that the rate of learning will too. (See Equations 33 and 34.) The five groups were definitely learning at different rates, a phenomenon incompatible with the $W = 0$ value observed. In a follow-up study, Atkinson, Bogartz, and Turner (1959) observed essentially the same results. Although the theory could be used to predict the results as a function of β correctly, even if it failed for various π values, it could not be used in a later study in which Juliet Popper Shaffer (1963) fixed $\pi_{11} = 1.0$ and $\pi_{21} = .5$ but varied β for three groups, $\beta = .33$, .50, and .67. Shaffer noted that $P(A_{1,n} \mid T_{1,n})$ and $P(A_{1,n} \mid T_{2,n})$ should be linearly increasing functions of β with equal slopes and that the difference between them should be constant for the three β values. (See Equations 35 and 36.) She found that $P(A_{1,n} \mid T_{1,n})$ increased linearly as expected, but that $P(A_{1,n} \mid T_{2,n})$ decreased. Thus, the slopes were not equal nor was the difference a constant. These experiments have raised theoretical questions that have had a wide influence on the development of learning theory. The main fault of the theory is that subjects are only temporarily influenced by the common stimulation. If the model is to be correct, the stimuli T_1 and T_2 must provide a common

stimulation that cannot be ignored by the subject (see Uhl, 1964; Halpern & Moore, 1967).

There are obvious problems with the extensions of SLT into discrimination learning by humans. The main difficulty seems to be that human beings have a much better analytical ability than that assumed by the model. Further theoretical ideas derived from SLT have been suggested as alternative solutions to discrimination learning. Among these are the pattern model (Estes, 1959a) and one of its variants, the mixed model (Estes & Hopkins, 1961; Atkinson & Estes, 1963). These are discussed in the section on paired-associate learning.

Stimulus compounding Any learning theory should be able to make predictions about behavior in new situations based on given information about the subject's behavior under similar or more elementary situations. For example, if a subject makes an A_1 response to stimulus S_1 with the probability p_1, and an A_2 response to stimulus S_c with probability p_c, how will he respond if the two stimulus situations are combined, T_1, and presented simultaneously? The solution suggested by SLT is given in Equation 33. In any stimulus-compounding experiment, the weights of the stimuli must be considered. SLT does this through the product of the set size and the sampling probability $N\theta$. Of course, the proportion of conditioned elements in each set influences the response probability also.

One important use of the compound-stimulus analysis is to estimate the weight of a stimulus set. Let us consider an example in which the problem is to estimate N_1 and N_2. Assume that T_1 and T_2 have no common stimulation. If $\theta_1 = \theta_2$, and through training, $P(A_1|T_1) = 1$ and $P(A_1|T_2) = 0$, then, when presented together, $P(A_1|T_1 \text{ and } T_2) = N_1/(N_1 + N_2)$. Thus, their relative sizes can be estimated. Of course, more elaborate procedures can also be used to estimate each value of θ.

Schoeffler (1956) ran a compound-stimulus study involving three sets of lights, two of which were first discriminated in a classical discrimination experiment. The sets were defined by partitioning 24 lights on a panel into three equal subsets of size 8. Then subset T_1 was reinforced with O_1 and T_2 with O_2, where O_1 and O_2 were event lights indicating which of two responses was correct. Subset T_3 was never presented. Discrimination training consisted of presenting all eight lights of each set with $\beta = .5$. After discrimination training (which was described very satisfactorily by the discrimination model discussed earlier) stimulus compounds were formed by combining at random n_i lights from each of the T_i sets. Because the three sets were randomly determined uniquely for each subject, and because of the homogeneity of the lights themselves, the assumption that the theoretical stimulus set, S_i associated with T_i, had an equal number of elements could be made. On test trials, no reinforcement was presented. The stimulus set that was not presented during discrimination training (T_3) was assumed to have its elements conditioned with a probability of .5 to each response. The expectation for an A_1 response, assuming $P(A_1|T_1) = 1$ and $P(A_1 \mid T_2) = 0$ was simply $(N_1 + .5N_3)/N_1 + N_2 + N_3)$. Only the data for one test pattern out of nine were significantly different from expectation. These results may not seem too surprising, but remember that the behavior exhibited is by no means the most rational. To maximize correct responses, the subjects should respond A_1 if $N_1 > N_2$, A_2 if $N_2 > N_1$, and ignore N_3 elements. However, if each subject had a deterministic response rule for each pattern depending in some way on the elements he attended to, the proportions would then represent the proportion of subjects and not a response probability for each subject. Further work is needed to evaluate this possibility. Once again we have the problem of interpreting average data.

The Estes, Burke, Atkinson, and Frankmann experiment (1957) investigated two aspects of SLT: probabilistic discrimination and compounding of stimuli. The T_i trial was followed by O_i on all trials, but the stimuli selected

varied. Twelve stimuli were evenly spaced around a circle, and were designated randomly by the numerals 1 through 12. Then the probability of selecting light i on a T_1 trial was $5i/78$ and the probability for a T_2 trial was $(65 - 5i)/78$. Two groups were run: The β probability was .50 for one group and .25 for the other. After 520 training trials, triads of lights were presented. The proportion of correct responses observed may have been slightly higher than that predicted for the two groups but was not significantly so. For $\beta = .50$, the observed proportion was .67, and the predicted proportion .64, whereas for $\beta = .25$, the observed proportion was .74 and the predicted .72. All these are well below the maximum possible correct proportions. Response proportions to individual lights presented during the test trials were systematically related to the reinforcement probability for each light, indicating probability-matching for the individual components of the stimuli. The slight regression observed toward .50 for the signal lights with high or low π values would be expected if there were some background stimulation that was not taken into account in the matching prediction. All in all, SLT is not perfect in its description of classical and probabilistic discrimination or in its account of stimulus-compounding, but the overall handling of the data is impressively good.

Stimulus generalization According to Estes' early development of SLT, stimulus generalization was to be accounted for by considering the stimulus as a series of overlapping sets. The normal procedure in generalization experiments is to train a subject to respond A_1 to stimulus T_1 until $P(A_1 | T_1) = p_i$. Then a similar stimulus T_1^* is presented. There is usually a decrement in the probability of the A_1 response; that is, $P(A_1 | T_1^*) < P(A_1 | T_1)$. If the stimulus situation associated with T_1 is conceived of as being composed of a set of elements, some of which are also included in T_1^*, then as A_1 is conditioned to T_1, A_1 is also conditioned to part of T_1^*. The degree of conditioning depends on $T_1 \cap T_1^*$, which in the discrimination experimental situation is the set S_C^*.

Generalization is usually treated along either quantitative dimensions or substitutive dimensions (prothetic or metathetic dimensions, according to S. S. Stevens, 1957). Both of these dimensions have been treated from the point of view of set theory (Restle, 1961; Atkinson & Estes, 1963). We confine our discussion to a sketchy presentation of the metathetic dimension. First, note that a general measure of overlap will produce stimulus generalization but will not specify the form of the generalization gradient. A set of stimuli T_i^* on some physical dimension A, such as wavelength of light or frequency of tone, is presented after the subject has been trained to a specific value T. Because the basic notion here is one of substitution, each set of elements associated with a stimulus different from the one originally conditioned is assumed to have some new and perhaps some common elements. A further assumption is that, as the physical stimulus is systematically increased or decreased, the sets of stimulus elements introduced are correspondingly related in a linear way. These ideas are spelled out in greater detail by Atkinson and Estes (1963).

Three axioms define a linear array of sets (Restle, 1961). If $T_i^* \leq T_j^* \leq T_k^*$ are ordered on some substitutive dimension, then $S_i \cap S_k \subseteq S_j$. In other words, this axiom states that, if an element belongs to any two sets, it also belongs to the sets in between. The second axiom states that, if the intersection of S_i and S_k is not null ($S_i \cap S_k \neq 0$), then $S_j \subseteq (S_i \cup S_k)$. The second axiom requires that all elements of any set between two nondisjoint sets belong to one or the other of the two sets. Finally, the third axiom states that all sets S associated with T stimuli have the same number of elements ($N_i = N_j = N$). The first task in any application of this theory is to establish a set of stimuli T_i that meet the requirements of the above axioms. Then tests of the generalization process in conditioning can be carried out.

Two generalization experiments have been

carried out using human subjects and a probability learning task in which the substitutive dimension of the position of a light stimulus along a line was used. LaBerge (1961) trained subjects on a vertical dimension by reinforcing T_1 with O_1 and T_2 with O_2 on all of the trials. Test stimuli given between these two stimuli showed very orderly response characteristics that were quite linear for individual subjects. When the two stimuli were widely spaced, the generalization function showed a plateau at the centrally located stimuli. As would be expected, the gradients were steeper when T_1 and T_2 were closer. The average generalization gradients were somewhat sigmoid in shape (which unfortunately could be due to averaging of subjects with different slope gradients). LaBerge found that latencies increased monotonically with distance from the training stimulus. No attempt was made to test SLT in this experiment.

The second experiment (Teresa Carterette, 1961) involved summated generalization. The stimuli consisted of a $2\frac{3}{4}$-in. square of light presented on a horizontal line in $\frac{1}{2}$-in. steps. Each block of trials began when the experimenter presented and identified for the subject first stimulus *A* and then stimulus *B*. Eight test trials were then given, on which either *A* or *B* or some other stimulus might be given. The subject's task was to distinguish between training stimuli *A* and *B* and the other presented stimuli. Two predictions from the theory were supported. First, the level of responding to test stimuli between training stimuli decreased as the training stimuli were spread further apart. Second, the slopes of the gradients on either side of the training stimuli were parallel for different groups. In contrast, gradients between the two training stimuli were shallower than predicted, and the range of the generalization was greater than expected. All in all, the theory did not do badly, but further testing is certainly called for because few assumptions of the generalization model have been experimentally tested.

Stimulus fluctuation This is not the place for an extensive review of stimulus fluctuation, but the student should at least be aware of this development in SLT and probability learning. More detailed discussions may be found in Estes (1955, 1959b). SLT predicts that,
Figure 20.7. Schematic diagram showing the fluctuation model of SLT applied to a simple forgetting experiment. (See text.)

as the stimulus conditions increase in variability, learning will be slower. An early study by Burke, Estes, and Hellyer (1954) supported this notion, but the Estes and Burke (1955) discrimination study, the study by Friedman et al. (1964), and a replication of the Burke, Estes, and Hellyer study by Anderson (1966) have raised serious doubts as to whether this prediction is generally true. In none of these experiments did variability function as consistently as predicted.

By assuming sets of stimulus elements that change over time, stimulus fluctuation is also used to account for such processes as forgetting, spontaneous recovery, distribution of practice effects, trace conditioning, and drive factors. We shall use a simple model of forgetting as an illustration. Figure 20.7 shows the theoretical changes in stimulation over time that can account for a decrease in response proportions over time. We assume that the total stimulation consists of a set of elements S that are available for sampling and another set S' that cannot be sampled from at the moment. Within each time interval Δt, arbitrarily specified but of a sufficiently long duration to observe the changes taking place, each element in S has a probability j of entering S', and each element in S' has a probability j' of entering S. Let $f(t)$ be the probability that any given element is in S at time t. Then

$$f(t+1) = f(t)\,(1-j) + [1-f(t)]j' \quad (40)$$

An element remains in S with probability $1-j$ and an element in S' enters S with probability j'. This is a simple linear difference equation as observed in Equation 10. It has the solution

$$f(t) = J - [J - f(0)]\alpha^t \quad (41)$$

where

$$J = \frac{j'}{j+j'} \quad \text{and} \quad \alpha = (1 - j - j')$$

The j and j' values are between zero and 1 and thus α is between -1 and $+1$. Eventually, α^t will decrease to zero and the asymptotic probability that an element is in S will become J. If there are N^* elements in $S \cup S'$, then N, the number of elements in S, is determined by the relation $N = JN^*$. The number in S' can be designated N', so $N^* = N + N'$.

The purpose of the fluctuation model is to determine response probability after a time interval when we have information about the initial response probability. Assume that the N elements in S are conditioned so that a proportion p_0 is associated with the A_1 response in the $t = 0$ time interval. Of the original N elements in S,

$$Nf(t) = N(J - (J-1)\alpha^t) \quad (42)$$

elements will still be in S after t time intervals. These elements that remain in S will be conditioned with probability p_0, so that $p_0Nf(t)$ conditioned elements are in S that were in S at time $t = 0$. Likewise, if a proportion p_0' elements are conditioned in S' at time $t = 0$, then, after t intervals of time $p_0'N'f'(t)$ conditioned elements are in S that were in S'.

The probability $f'(t)$ is computed by setting $f(0) = 0$ in Equation 41 because this is the probability that elements in S' are in S after t intervals of time: $f'(t) = J(1 - \alpha^t)$. To compute the probability of a conditioned response at time t, p_t, we must determine the proportion of conditioned elements in S. There are N elements in S, so

$$p_t = \frac{1}{N}[p_0Nf(t) + p'N'f'(t)] =$$
$$p_0(J - (J-1)\alpha^t) + p_0'(1-J)\,(1-\alpha^t). \quad (43)$$

In the case of simple conditioning, we might assume that $p_0 = 1$ and $p_0' = 0$. Then response proportions will decrease to an asymptotic level, p_0J. Because J depends on the ratio of the elements available for sampling to those that are not available, the amount of forgetting is a function of the amount of stimulus change. In Figure 20.7, $j = .20$, $j' = .10$, so $J = .33$, $N = 6$ and $N' = 12$. Before training, all elements are assumed to be unconditioned. After training, at $t = 0$, all six elements in S are conditioned.
Figure 20.8. Trial paradigm for contingent reinforcement in probability learning. π_{ij} is the probability of an O_j outcome following an A_i response. (See Figure 20.1 for noncontingent paradigm.)

Two steps in the forgetting process are plotted by the formula $p_t = .33 - (.33 - 1.0)(1.0 - .20 - .10)^t$, where $p_0 = 1.0$ and $p_0' = 0$. The first step, at $t = 4$, leaves a proportion of about .50, the second, at asymptote, leaves a proportion .33.

Further Developments of SLT: Reinforcement Contingencies

Contingent reinforcement Thus far, we have limited our discussion to the noncontingent reinforcement procedure in which $P(O_1) = \pi$, independently of the subject's response and the trial number. The contingent reinforcement schedule defines a different probability for each of the two responses. Figure 20.8 is a schematic diagram of this procedure, in which the reinforcement of the A_i response is probabilistically determined by $P(O_j|A_i) = \pi_{ij}$. Again, the reinforcing event is directly associated with the experimental outcome, E_i with O_i. The learning curves for this situation are developed in a manner completely analogous to that for Equation 10.

Operator Applied	*Probability on Trial n + 1*	*Probability of Applying Operator*
L_1p_n	$(1-\theta)p_n + \theta$	$p_n\pi_{11}$
L_2p_n	$(1-\theta)p_n$	$p_n(1-\pi_{11})$
L_1p_n	$(1-\theta)p_n + \theta$	$(1-p_n)\pi_{21}$
L_2p_n	$(1-\theta)p_n$	$(1-p_n)(1-\pi_{21})$

By averaging these changes in probability, the average change in probability over each trial is determined:

$$p_{n+1} = [1 - \theta(\pi_{12} + \pi_{21})]p_n + \theta\pi_{21} \qquad (44)$$

which has the solution

$$p_n = \bar{\pi} - (\bar{\pi} - p_1)\,[1 - \theta(\pi_{12} + \pi_{21})]^{n-1} \qquad (45)$$

where

$$\bar{\pi} = \frac{\pi_{21}}{\pi_{12} + \pi_{21}}$$

Because the expected asymptote $\bar{\pi}$ is not particularly intuitive, subjects would not be expected to "compute" it in any ordinary sense. However, the theory implies that $\bar{\pi}$ is the asymptote that will be reached with the contingent procedure. The data from early studies with contingent reinforcement did not always attain this asymptote. However, in some cases, the contingency was set up so that the subject was to select a response that would turn on a single light. It is important in the application of the model to ensure that every trial be followed by O_1 or O_2, and that the two outcomes lead unambiguously to reinforcements E_1 or E_2 (*determinate reinforcement*). If the light did not go on, the subject might or might not have assumed that the other response would have turned on the light. Actually, in this schedule, without two explicit outcomes, it is possible that neither response might turn on the light. Let O_1 represent the instance in which the light is turned on and O_2 that in which the light is not turned on; then $p_n\pi_{12} + (1 - p_n)\pi_{22}$ is the

probability the light will not be turned on. If the π_{i2} values are large, subjects may detect the fact that the light comes on very infrequently. Then, covertly, a third reinforcing event may occur, namely, one that occurs when the subject covertly responds to no outcome with the interpretation that neither response would have turned the light on. (Reinforcement situations without clear assignments of outcomes are referred to as *indeterminate reinforcement situations.*) This interpretation of the effects of instructional and procedural changes is supported by the pattern of results observed in experiments by Detambel (1955), Brand, Woods, and Sakoda (1956), Woods (1959), and Koehler (1961).

In a study on noncontingent PL, Reber and Millward (1968) asked two groups of subjects simply to observe outcomes for 500 trials, one group at the rate of one outcome every 4 sec, and the other group at the rate of two outcomes every sec. Following the simple observation trials, subjects were asked to predict for another 500 trials in a manner similar to noncontingent PL. Neither group differed in the asymptote they attained or in runs statistics from a group tested under a regular prediction procedure. (Figure 20.5 presents the data of the control group from which the two observation groups did not differ.) The sequential statistics differed across groups, but the difference is not systematically related to observation versus regular PL. During the 500 prediction trials, both groups remained at a stable asymptote of about .84 for $\pi = .80$. Lambe (1968) used the observation procedure to investigate the contingent reinforcement schedule. The subjects were first brought to asymptote by observation trials at $\bar{\pi}$, and then the contingencies were introduced. The two groups of primary interest had reinforcement values: (1) $\pi_{11} = .6$; $\pi_{21} = .8$, and (2) $\pi_{11} = .8$; $\pi_{21} = .4$. In both cases, $\bar{\pi} = .67$. In Group 1, outcomes tended to reinforce the opposite response from the one predicted, whereas in Group 2, the outcome predicted was very likely to be reinforced. Lambe was interested
Figure 20.9. Learning curves from contingent and noncontingent probability-learning paradigms.

in whether these different schedules, both of which had the same expected asymptote, would remain at the initial response probability established through the observation of outcomes. Figure 20.9 presents the results for the 500 trials after observation trials for Group 1, Group 2, and Group 3, a noncontingent control group with $\pi = .67$. Note first that the subjects begin at about .67, showing that the observation trials were effective in establishing asymptotic responding. Second, the three groups remain at asymptote after an initial rise over the first 100 prediction trials. The asymptotes from trials 101 to 500 are not significantly different, but the rise from trial 1 to trial 100 is significant. The asymptote is not $\bar{\pi}$ as predicted, but rather a slight overshooting of $\bar{\pi}$ very similar to that observed in the results by Reber and Millward (1968) (see Figure 20.5).

"Blank" trials Another variation in reinforcements related to the contingent procedure is the effect of so-called "blank" trials. A trial in PL is usually followed by an O_1 or an O_2. On blank trials, neither O_1 nor O_2 occurs (the O_0 outcome). From the subject's

point of view, it is an ambiguous outcome and therefore the experimenter cannot a priori associate a reinforcing event with O_0. A number of experiments have been run to determine the effect of O_0 on response probability. An early study by Neimark (1956) led to the formulation of the identity hypothesis, that is, the hypothesis that no change occurred on O_0 trials. Later studies that relied on asymptotic responding to determine whether or not the O_0 outcome had an effect have found that the identity operator L_0 yields the best fits. Atkinson (1956) and Millward (1967), using contingent reinforcement schedules, found that $L_0 p_n = p_n$, applied on O_0 trials, adequately described the asymptotes. On the other hand, investigators who looked at sequential statistics have found that the O_0 outcome produces changes in p_n. Anderson and Grant (1957, 1958) suggested from sequential statistics applied to double-outcome trials (that is, trials on which both O_1 and O_2 occurred) that there was a regression to .5 on double-outcome trials. LaBerge, Greeno, and Peterson (1962) and Greeno (1962) equated groups on the total number of O_i, $i = 1, 2$, outcomes received, but gave different groups different numbers of O_0 outcomes. A neutral or identity hypothesis would predict that the groups would all be the same when the response proportions were plotted according to O_1 and O_2 trials received. They were not. In both papers, the conclusion was that there was a regression to .5. Greeno further concluded that the regression was controlled by the outcome frequency and not by the response frequency. By using different payoff schedules, he stabilized groups with the same outcome probabilities at different response probabilities. One interpretation of the identity hypothesis is that it amounts to no change on the average, although each subject may change after an O_0 outcome. If the effect of an O_0 depended on the p_n value, so that $p_{n+1} = (1 - \theta)p_n + \theta$ with probability p_n, and $p_{n+1} = (1 - \theta)p_n$ with a probability $1 - p_n$, then, on the average, $p_{n+1} = p_n$. The probability of each subject might change, depending on the response he made. Greeno's results provide evidence against this hypothesis and in fact against the identity operator in general. However, the picture is still not completely clear because it is not known whether the O_0 outcome reduces p_n all the way to .5. In the Reber and Millward experiment (1968), 500 trials of only O_0 outcomes reduced asymptotic responding from about .84 to .80. This is certainly not a very large effect and does not agree with the Greeno results.

Amount of reward One topic of wide interest in PL has been the role of the amount of the reward given subjects. The usual simple procedure is to reward the subject with money or points when he is correct and to take away money or points when he is wrong. Under symmetric payoff, all correct responses and all wrong responses are rewarded equally and penalized equally. In general, under symmetric payoff conditions, asymptotes are well beyond the matching values although maximizing still does not take place. Under differential payoff, each response has a specified payoff and loss associated with it. One of the most interesting findings in this area of research is the usefulness of the idea of "regret." Myers and Atkinson (1964) have applied a weak-and-strong conditioning model (a derivative of stimulus-sampling theory) to payoff studies with quite satisfactory results. When various amounts of reward are presented, we might assume that each reward value would have a certain reinforcing effect, positive or negative. However, this does not seem to work. Instead, Myers and Atkinson calculated the difference between what was obtained and what might have been obtained if a different outcome had occurred. This difference, or regret, seems to determine the reward value of the payoff (see Myers, Suydam, & Heuckeroth, 1966).

Other procedures We mention briefly two other procedures simply to illustrate the breadth of the application of ideas originating

in SLT. Suppes and Zinnes (1961, 1966), Suppes and Frankmann (1961), and Suppes, Rouanet, Levine, and Frankmann (1964) have extended the linear operator models to a situation in which the subject responds, not from a finite set of responses, but on some continuum. In their book (1960), Suppes and Atkinson have presented a series of experiments on two-person interactions. These involve a situation very much like PL but in which the probability of a reinforcing outcome depends on the responses of both subjects. In this sense, a contingent procedure is involved. Other studies by Burke (1959, 1960, 1962) have further developed the two-person interaction area.

Special Approaches and Studies

The role of event sequences The most salient features of PL not properly accounted for by SLT all involve aspects of the sequence of events. In fact, almost all attempts to account for PL learning (except SLT) have heavily emphasized the role of past events in determining what a subject will predict (see Hake & Hyman, 1953). For example, very early in the history of experimental work in PL, Goodnow (1955) suggested that what subjects recognize on a trial is the run of events. One advantage of an analysis in terms of runs is that the stimulus situation is made relatively more complex but not as unwieldy as it would be if it included all stimulus patterns. Restle (1961) suggested that runs of events were of primary importance and built them into a theoretical structure for PL that predicted negative recency. He assumed that the probability of an A_1 response after a run of m O_1 events ($O_2O_1O_1O_1 \ldots O_1$) would be equal to the number of times that such a run was followed by an O_1 event in the past history of the experiment weighted by the run length itself. For preasymptotic data, we can compute the function directly from the event sequences involved. The theory thus has the advantage of being able to handle any kind of sequence. However, while Restle was developing his schema theory, Friedman et al. published their results (1964), showing relatively good positive recency for runs up to length 5. Restle's theory could still handle these results because he took into account the past training sequence, which involved a number of different π values. Nonetheless, the theory was in for difficulty, and the following studies illustrate the problems.

The first study was that by Witte (1964), who was testing two ideas mentioned earlier. One was Anderson's contention (1964) that various reinforcement probabilities have long-term effects. Witte introduced sequences of Markov-chain event probabilities on the first day of training. One group had perseverance of similar events, leading to long runs (where $P(O_{1,n+1} | O_{1,n}) > P(O_{1,n})$ and $P(O_{2,n+1} | O_{2,n}) > P(O_{2,n})$). The other group had alternation of events, leading to short runs (where $P(O_{1,n+1} | O_{1,n}) < P(O_{1,n})$ and $P(O_{2,n+1} | O_{2,n}) < P(O_{2,n})$). A control was also run without outcome contingencies. Witte's first conclusion was that, after a sufficient number of random reinforcement trials, we cannot detect in the response proportions differing earlier histories of reinforcement. Witte's conditional probabilities $P(A_{1,n+1} | O_{i,n})$ were in agreement with the Burke and Estes theory (1957). However, even after 1200 trials, the early difference in runs showed up in the recency analysis; the perseverance group showed strong positive recency and the alternation group only moderate positive recency. Nonetheless, the presence of positive recency and the lack of any difference in alternation responding for the three groups seem to discount Anderson's argument against the Friedman et al. experiment (1964). Although SLT did not accurately describe the runs statistics even after extended trials, the strong negative recency predicted by Restle simply did not take place. Furthermore, the problem with SLT seemed to be one of parameter values. The curve could have been described if the learning parameter had been estimated from the recency data and not from the asymptotic training data.

The second experiment was performed by

Restle (1966) to test his own theory about the effect of runs. It is a neat and ingenious experiment and worth discussion as an example of how exact models can be decisively discarded. His design consisted of presenting subjects with a sequence of events consisting of only two run lengths (for example, 11 22 11 22222 11111 22 11111 22222 11). Another example might be (1 2222 1111 2 1111 2 1 2 1111). The first group has runs of length 2 and 5 (2,5) and the second group has runs of length 1 and 4 (1,4). If the probability of the two kinds of runs is varied, Restle's theory can be made to predict various response probabilities for the response on the trial immediately after two events in a row—the only trial that has to be guessed. If a 1 follows two 1's on 50 percent of the trials, then the subject has a response probability of $\frac{2}{7}$ of predicting a 1. (The run of length 2 has weight 2, and the run of length 5 has weight 5; because each is equally likely, the ratio is determined.) These predictions were compared with those of (1) a stimulus-conditioning hypothesis proposed by Greeno and (2) a 1-trial contingency hypothesis. Greeno's hypothesis looks at each run sequence $O_{2,n}O_{1,n+1}O_{1,n+2} \ldots O_{1,n+k}$ as consisting of $k + 1$ distinct run stimuli: $O_{2,n}$; $O_{2,n}O_{1,n+1}$; $O_{2,n}O_{1,n+1}O_{2,n+2}$; . . . $O_{2,n}O_{1,n+1}O_{1,n+2} \ldots O_{1,n+k}$. He assumed that when $O_{2,n}$ occurred and was followed by $O_{1,n+1}$, the latter reinforced A_1 as a response to $O_{2,n}$. Also, when $O_{1,n+2}$ occurred, it reinforced the A_1 response to both $O_{2,n}$ and $O_{2,n}O_{1,n+1}$ run stimuli. In the same manner each of the other run stimuli was successively reinforced by later outcomes of the run. The process stopped when the run changed; that is, the last reinforcement for all run stimuli listed would be the $O_{2,n+k+1}$ outcome. This would then start a run of O_2 outcomes which would be similarly reinforced.

The third hypothesis considered by Restle in this experiment assumed that, in ambiguous situations such as those that exist after a run of two events in the 2- and 5-run string mentioned earlier, subjects may simply pay attention to the 1-trial event contingency, that is, $P(O_{1,n+1}|O_{1,n})$. The three hypotheses differ in the nature of their dependency on run structure: The Restle hypothesis depends on the ratio of the run lengths, the Greeno hypothesis on the difference of run lengths, and the simple 1-trial contingency hypothesis on the average run length, or the sum. Restle ran four groups with equally frequent run lengths (1,4), (2,3), (2,8), and (6,9). The runs for the first and the third groups are in the same ratio, as are those of the second and the fourth. If the ratio hypothesis is correct, these pairs should perform alike. The first and fourth groups have the same difference, the second is smaller, and the third much larger. According to the Greeno hypothesis, the groups should be ordered $(2) < (1) = (4) < (3)$. If the contingency hypothesis is correct, the first and second should be the same, but the third and fourth should show increasing learning difficulty. Restle's results unambiguously supported the contingency hypothesis. Interestingly enough, the subjects did not learn perfectly the contingencies concerning the events on unambiguous trials (that is, within the runs).

In an experimental analysis of sequential learning by Keller (1963), the routine was not exactly that of PL because a given sequence such as 11010001 was repeated successively. However, the routine is of interest to PL, for it involves the manner in which subjects encode the stimulus sequence. Keller had subjects learn sequences of a fixed length repeated over and over without a break. He found that the total number of errors was a simple mutiple of the number of runs and that errors occurred at the junctions between runs.

In an attempt to analyze such learning, Restle (1967) introduced the idea that the subject encodes the runs of the sequences. That is, the subject develops a kind of "generative grammar" for the event runs. For cases where alternative "grammatical" rules are possible, Restle considered the idea that the subject generates second-order rules indicating how to apply the first-order rules. One

such set of second-order rules would be in terms of runs of runs. One problem with this analysis is that sequences can be written requiring even higher-order runs of runs; such sequences would necessitate the postulation of third- and higher-order runs of runs—a seemingly rather unlikely phenomenon. Thus, Restle discounts the second-order rule idea for a general subsequence theory that is less exact but intuitively more appealing. It is a second-order rule, not in terms of runs, but rather in terms of easily encoded patterns. Restle makes the point that first-order rules seem to be learned as a 1-stage or all-or-none process, whereas second-order rules are learned by a 2-or-more-stage process.

The importance of runs for subjects' memory of the event structure has received support from a study by Millward and Reber (1967). On each trial n, subjects were required not only to predict the next event E_{n+1} but to try to recall the event on a past trial $n - x$. The variable x ranged from 1 to 9. Different groups were defined by the frequency distribution of x that was used. Three results were observed. The first was that when the probe was limited to only five trials back ($x = 1,2,3,4,5$) or when it occurred more than 50 percent of the time with $x = 1$, 2, or 3, the $P(A_1)$ response was nearer .5 than when x emphasized trials farther back than $5 (x > 5)$. This seems to imply that, if subjects attend to long sequences of events, they tend to overshoot more. Second, the recall of events x trials back depended more on the number of runs intervening between $n - x$ and n than on the value of x itself. Adding one more run almost linearly decreased the recall probability for 1 to 4 runs. The third result was that the guessing probability for events on trial $n - x$, when the event presumably was not known, matched the probability of the event. This provides an example of probability matching in reverse and seems to support a type of conditioning model that assumes that the effect of reinforcing events is to develop some simple response strength.

Rose and Vitz (1966) investigated two models for PL. One was the Restle model assuming that subjects encode the runs of events. The other model was the component model in which each pattern of events k trials back is considered a stimulus component. Rose and Vitz ran a standard PL experiment except that specific event patterns were included. For example, no runs of length 3 occurred (that is, 0111 was always followed by 1 and 1000 was always followed by 0). They found that, although the runs model was better than the component model, it failed because more than the previous run was encoded and subjects did utilize information about the run that preceded the run in progress. They also found that the memory for the preceding run is better if the run is long. Confusion of patterns occurred, indicating another factor that must be considered in any theory based on runs.

Feldman and Hanna (1966) ran a study involving discrimination of event sequences in which they generalized the idea that subjects encode event runs to the idea that they encode a number of event pattern types and encode in a way that depends on the sequence itself. The theory is too complicated to discuss here, but it will influence future work because the emphasis in PL at present is on analysis of encoding structures developed by subjects during a PL experiment.

The experiments just discussed indicate that runs are particularly important in learning responses to sequences, although the findings have not yet been incorporated into a theoretical structure with the predictive power of SLT and its variants.

The N-element pattern model The earlier version of SLT regarded the stimulus environment as consisting of N elements, any of which could be sampled on every trial. In the pattern model, N is generally considered to be relatively small and only one element is sampled on each trial. The pattern model also introduces a different reinforcement axiom: Instead of assuming that the E_i reinforcing event changes the conditioned state of the

sampled element so that it is conditioned to the A_i response, the E_i event produces such a change with a probability c. Thus, every reinforced trial does not automatically produce a change in the number of conditioned elements. Instead of linear operators, Markov-chain analysis is used in the development of the model (see the section on concept learning). In contrast with the linear model, the pattern model assumes that $P(A_{1,n+1} | E_{1,n}A_{1,n}) = P(A_{1,n})$. The reason for this is that, for the $A_{1,n}$ response to occur, an element conditioned to the A_1 response must be sampled. The E_1 reinforcing event cannot change its conditioning state and therefore no change in response probability can occur.

The predictions of the linear model with respect to the asymptotic variance of A_1 responses have received little empirical support. The linear model always predicts too small a variance. Although all simple statistics derived from the pattern model and the linear model are identical, the pattern model predicts a larger variance in asymptotic response proportions and agrees better with observed results. It therefore appears that the N-element pattern model is a better underlying model for PL than the linear-operator model.

Yellott (1965) attempted to make a more definitive test of the two models discussed above, using a noncontingent-success procedure (NCS). The procedure involves contingent reinforcement in which, instead of determining the probability of an O_i outcome, the experiment specifies the probability of presenting the O_i outcome if the A_i response is made. Let $P(O_i | A_i) = d$, $i = 1,2$. If $d = 1$, then on every trial the subject is presented with the outcome that he predicts. If $d = 0$, he is always presented with the opposite outcome. Under this reinforcement procedure, Yellott found that the N-element pattern model and a variant of the linear-operator model with two parameters made two quite different but easily tested predictions. To consider one rather crucial difference, let us take the predictions of the probability of an alternation after m NCS trials with $d = 1$. An alternation is defined as $P(A_{i,n+1} | A_{j,n})$, where $i \neq j$; $i,j = 1,2$. The interest here is in the probability of an alternation as a function of the number of trials on which a subject has been correct in his prediction. Of course with $d = 1$, he is always correct. If, before the m success trials, the subjects are at an asymptote of π and there are N elements, the alternation statistic is

$$P\text{ (alternation} | N\text{-element model)} = 2\pi(1 - \pi)\frac{(N - 1)}{N}$$

In contrast, if we assume that the subjects are at asymptote but are responding according to the linear model, then

$$P\text{ (alternation} | \text{linear model)} = 2(1 - \theta)[P(A_{1,\infty}) - P(A^2_{1,\infty})](1 - \theta^2)^{m-2}$$

Note that the linear model statistic is a function of m, the number of successes in a row, whereas the N-element model is not. The alternation statistic of the linear model decreases as a function of m until it reaches zero while the N-element model statistic remains constant for all m. The NCS schedule makes a very sharp difference in the predictions of these two models. Other statistics usually computed with the standard PL procedure do not differentiate between the models. Yellott found that alternations did not decrease over repeated success trials. Thus, his results support the N-element pattern model over the linear-operator model. Many other statistics tested against the pattern model gave excellent overall results.

This example illustrates that, although subjects seem to be fairly cognitive in their behavior in the PL routine, a generally path-independent conditioning model handles most of the fine structure accurately. Furthermore, SLT and its derivative theories have led to the development of various kinds of routines and have described the results of these new procedures quite adequately. This is not to claim that all aspects of PL are handled perfectly by SLT or SST. It is the task of the theoretician to bring the cognitive aspects

into the picture, not so much as an alternative to SLT, but as a supplement to it so that the failures of SLT that are apparently due to cognitive aspects of behavior can be handled.

CONCEPT LEARNING

Definition of a Concept

A concept has been defined as any rule that allows a set of stimulus objects to be classified into two or more mutually exclusive subsets representing exemplars of the concept. Because the definition of a concept is intimately tied to the definition of a stimulus, we must discuss briefly what is meant by the term "stimulus" before we can attempt to refine this definition of a concept. Most stimuli used in learning studies are composed of a number of different elements, cues, and/or dimensions. That is, most stimuli can be responded to on the basis of a number of different characteristics. Now if a theory is to describe behavior, it must state the nature of the stimulus exactly, for the stimulus is one of the fundamental independent variables in learning experiments. Furthermore, not only must the physical stimulus be defined for the theory but also the stimulus as perceived or encoded by the subject. In an attempt to deal with conceptual behavior independently of the way in which the subject perceived or encoded the stimulus, Hovland (1952) introduced a notation system that established an agreement between the experimenter and the subject about what the stimulus characteristics would be. Hunt (1962) has developed a more elaborate and exactly defined version of Hovland's notation system (see Restle, 1961; Banerji, 1962; Iverson, 1962; Hunt, Marin & Stone, 1966). Hunt's definition of a concept is presented here.

1. There is a universe of objects *U* that may be observed by the subject in a concept-learning experiment.

2. An attribute is a dimension along which objects can differ one from the other. Objects with the same attribute can differ according to the different values that they assume on the attribute.

3. A value is an equivalence class defined for an attribute. Some attributes are finite, in which case the value is simply that aspect of the attribute observed. However, if the attribute is infinite or continuous, then some set
Figure 20.10. Examples and descriptive space for a set of concept-learning stimuli. The three dimensions represented are shape, size, and filled-unfilled objects.

of possible observations must be classed together to denote a value. For example, if size is the attribute or dimension, we might make a classification by calling every object greater than or equal to some number *a* on the continuum "large," every object greater than or equal to *b* but less than *a* "medium," and every object less than *b* "small." For a given object, only one value may be assigned per attribute.

4. The description of an object is a statement defining the value of every attribute for that object.

5. A descriptive space is the set of all possible descriptions of objects. The universe may contain an object for every description or it may not. Every object has its point in the descriptive space.

Consider the set of stimuli in Figure 20.10. Eighteen objects are presented, constituting the universe *U*. The attributes of the objects are "shape," "size," and "filled versus unfilled." A verbal description of the first object might be "small unfilled circle," whereas a verbal description of the last might be "large filled square." We can define a vector, the *i*th element of which specifies the value of the *i*th dimension. If the dimensions are ordered "shape," "size," and "unfilled-filled," and if circle = 1, triangle = 2, and square = 3; small = 1, medium = 2, and large = 3; and if unfilled = 1 and filled = 2, the first object is described by (1, 1, 1) and the last by (3, 3, 2). The descriptive space can be represented by a matrix with columns for the attributes or dimensions and rows for values. However, to complete the matrix, null values, 0, have to be added to all dimensions that have values less than the dimension with the maximum number of values.

	Dimension		
Value	*Shape*	*Size*	*Unfilled-Filled*
1	1	1	1
2	2	2	2
3	3	3	0

In general, then, let there be *n* dimensions and let the maximum number of values on any dimension be *m*. Then a matrix ($m \times n$) describes the descriptive space in which each row without a null element corresponds to an object. If there are v_i values on the *i*th dimension, then there are

$$\prod_{i=1}^{n} v_i = N$$

objects in the descriptive space.

If the total set of objects in the universe is the set characterized by the descriptive space, then there are $2^N - 2$ binary concepts possible, corresponding to the $2^N - 2$ partitions of the *N* objects into two subsets. (A partition is a mutually exclusive and exhaustive division of a set of objects.) In this case, the partition is into two subsets, for one set corresponds to the set of objects that meet the definition of the concept and the other to those that do not—that is, the exemplars and nonexemplars of the concept. The two cases of objects that are all exemplars and objects that are all nonexemplars of the concept have been excluded because they are meaningless as concepts.

Note that, although these $2^N - 2$ partitions exhaust the ways of dividing up the objects into two classes, there can be many ways of defining a given partition. To illustrate these ideas more fully without dealing with astronomically large numbers, let us consider nine of the objects defined in Figure 20.10 (ignoring the unfilled-filled dimension). With only three values on two dimensions, there are still $2^9 - 2 = 510$ partitions. However, for the purposes of defining concepts in general, we are not particularly interested in the difference between the concept "all squares" and "all circles" because they differ only in the particular value and are logically equivalent.

Haygood and Bourne (1965) present a method for discussing concepts that, though limited, is helpful. Assume that the concept is to be defined by specifying some relationship between single values on each of two dimensions. (If there were more than two dimensions, the other dimensions could be ignored

or else the scheme could be generalized.) The two values are called the *focal values.* Let us consider a simple example: Let the universe of stimuli *U* be the stimuli defined by shape (circles, triangles, and squares) and size (small, medium, and large). A simple affirmative concept would be one that selected a single value on a single dimension. Whenever that value occurred, the stimulus would be an example of the concept, and whenever the value did not occur, the stimulus would not be an example of the concept. For instance, if we selected "squareness," the three square stimuli (small square, medium square, and large square) would constitute all examples of the concept, and the remaining six stimuli would not be examples. Now let us consider the conjunctive concept. Here, two focal stimulus values are chosen, say *A* and *B*, where *A* is a single value on dimension 1, and *B* a single value on dimension 2. According to the conjunctive rule, the stimulus is an example of the concept only when both values are present. Thus if "squareness" and "largeness" are chosen, only the single stimulus "large square" satisfies the concept and the other eight do not.

To introduce all the concepts that can be formed by this procedure, we must become slightly more abstract. Let us designate dimensions by 1 and 2 and values by *a, b,* and *c.* The nine stimuli are then (1) 1*a*-2*a*, (2) 1*a*-2*b*, (3) 1*a*-2*c*, (4) 1*b*-2*a*, (5) 1*b*-2*b*, (6) 1*b*-2*c*, (7) 1*c*-2*a*, (8) 1*c*-2*b*, and (9) 1*c*-2*c*. If the two

TABLE 20.3 CONCEPT RULES BASED ON LOGICAL CONNECTIVES

				Contingency Patterns Indicated				
	Name	*Symbolic Description*	*Verbal Description*	1 AB	2 $A\bar{B}$	3 $\bar{A}B$	4 $\bar{A}\bar{B}$	*Stimuli*
1a	Affirmation[a]	*A*	All *A* are +	+	+	−	−	1, 2, 3
		B	All *B* are +	+	−	+	−	1, 4, 7
1b	Negation[a]	$\bar{A}$	All $\bar{A}$ are +	−	+	−	+	4, 5, 6, 7, 8, 9
		$\bar{B}$	All $\bar{B}$ are +	−	−	+	+	2, 3, 5, 6, 8, 9
2a	Conjunction[b]	*A* & *B*	All *A* & *B* are +	+	−	−	−	1
2b	Alternative Denial[b]	$\bar{A}$ or $\bar{B}$	All $\bar{A}$ or $\bar{B}$ are +	−	+	+	+	2, 3, 4, 5, 6, 7, 8
3a	Inclusive Disjunction[b]	*A* or *B*	All *A* or *B* are +	+	+	+	−	1, 2, 3, 4, 7
3b	Joint Denial[b]	$\bar{A}$ & $\bar{B}$	All $\bar{A}$ & $\bar{B}$ are +	−	−	−	+	5, 6, 8, 9
4a	Conditional[b]	$A \rightarrow B$	If *A* then it	+	−	+	+	1, 2, 3, 5, 6, 8, 9
		$B \rightarrow A$	must be *B*	+	+	−	+	1, 4, 5, 6, 7, 8, 9
4b	Exclusion[b]	*A* & $\bar{B}$	All *A* & $\bar{B}$	−	+	−	−	4, 7
		B & $\bar{A}$	are +	−	−	+	−	2, 3
5a	Biconditional[c]	$A \leftrightarrow B$	*A* if and only if *B*	+	−	−	+	1, 5, 6, 8, 9
5b	Exclusive Disjunction[c]	*A* $\overline{\text{or}}$ *B*	All *A* or *B* but not *A* & *B* are +	−	+	+	−	2, 3, 4, 7

[a] Level I.
[b] Level II.
[c] Level III.

values 1a and 2a are the focal values A and B respectively, each stimulus can be characterized as containing A or not ($\bar{A}$), and containing B or not ($\bar{B}$). There are thus four combinations of the focal values: AB, $A\bar{B}$, $\bar{A}B$, and $\bar{A}\bar{B}$. These four combinations include all nine stimuli: AB = stimulus 1; $A\bar{B}$ = stimuli 2 and 3; $\bar{A}B$ = stimuli 4 and 7; and $\bar{A}\bar{B}$ = stimuli 5, 6, 8, and 9. Even if dimensions had more than three values and/or if there were more dimensions not involved in defining the concept, there would still be only four categories to consider. The generalization to concepts involving three or more dimensions is straightforward. With three dimensions, there would be eight basic combinations of focal values, ABC, $AB\bar{C}$, $A\bar{B}\bar{C}$, and so on.

The purpose of this scheme is systematically to reduce the $2^N - 2$ possible concepts to the definable logically distinct relationships. Table 20.3 presents these patterns for two dimensions with three values each. Of the 510 patterns, five basic concepts are described. These basic concepts are composed of two classes within each of the five concepts by taking advantage of the fact that, for each of the basic five, there is a complementary concept. The five basic concepts are listed in the rows of Table 20.3. The first column provides names for the relationships based on logic; the second column gives the relationship between the two focal values; the third column gives a simple verbal description of the concept; and the fourth column indicates the partition of the combinations used to define the concept. Thus, for example, negation has the pattern $-+-+$, which means that AB and $\bar{A}B$ combinations are not examples and that the $A\bar{B}$ and $\bar{A}\bar{B}$ combinations are examples.

Let us pursue this example further and consider again the set of nine stimuli illustrated in Figure 20.10. Assume that the focal values are A = smallness and B = circle. Then, the four combinations of "circle" and "smallness" are: "small circle," "small $\overline{\text{circle}}$," "$\overline{\text{small}}$ circle," and "$\overline{\text{small}}$ $\overline{\text{circle}}$," where the bar over a word means the absence of that value.

The partition for the negation concept $\bar{A}$ says that all $\bar{A}$ are examples of the concept (+). Thus $\overline{\text{small}}$ circles and $\overline{\text{small}}$ $\overline{\text{circles}}$ are examples of the concept. That is to say, medium circles, large circles, medium squares, large squares, medium triangles, and large triangles are examples. These are stimuli 4, 5, 6, 7, 8, and 9 as they were defined earlier and as presented in the last column of Table 20.3. The last column presents all the different possible partitions for the case when A and B are selected as the focal values. Of course, if A and B represented different focal values, other partitions, presumably equivalent to these, would be selected. Notice also that there are two equivalent partitions for each of the affirmative, negative, conditional, and exclusive concepts; this partitioning occurs because each concept involves the two focal values in an asymmetrical way.

We can now define a concept as a partition of the universe of objects. When n dimensions are involved, but only $r = n - i$ are used in defining the concept, the r dimensions are called "relevant" and the i dimensions "irrelevant." In the negative concept $\bar{A}$ above, shape is an irrelevant dimension. Irrelevant dimensions are those the values of which occur in conjunction with both defining and nondefining values of the relevant dimensions with equal probability. Although this scheme can be extended so that focal values are chosen for more than two dimensions, doing so makes the concepts extremely numerous and psychologically very difficult.

An important result of the Haygood and Bourne scheme for representing concepts is that it results in an ordered classification. Definite logical relations are specified, equivalence classes are apparent, and the logical relations can be ordered: Level I, unidimensional concepts; Level II, conjunctions and disjunctions of both relevant attributes; Level III, conditional and biconditional cases. Neisser and Weene (1962) noted earlier that each level can be defined in terms of the lower level. For example, $A \rightarrow B$ can be written $\bar{A}$ or B and $A \leftrightarrow B$ can be written [(A and B)

or ($\bar{A}$ and $\bar{B}$)]. More will be said about this classification scheme when results of experiments are discussed.

Two aspects of the classification scheme described above deserve further discussion. First, the idea of a single focal value limits the concepts to some extent. If there were four values on a dimension, it would be possible to define a concept that involved two values. Although this would require a new table analogous to Table 20.3, it would not be very different logically. We could simply define a new value consisting of the two values together. To consider an affirmative concept again, if there were four values on a dimension, we might define the concept as any stimulus containing either value 1 or value 2. To use shape as an example of the attribute, the values might be circles, squares, triangles, and ellipses, and the presence of circles or triangles might constitute the concept. In such a case, these two values could together be called *A* and the combinations relisted.

The second point concerns what might be called *multiple concepts*. Instead of a simple dichotomization of the set of objects, there is a multiple partition. For example, the following concepts might be defined: "red square," "not red square," "red not square," "not red not square." For each stimulus (for example, "red square"), the analysis just presented still holds. However, for all other stimuli that do not meet the criterion "red square," a further concept may apply (for example, "red not square"). One way to regard such concepts is as two independent concepts applied simultaneously so that the four-fold table C_1C_2, $\bar{C}_1C_2$, $C_1\bar{C}_2$, and $\bar{C}_1\bar{C}_2$ results, where C_i is concept *i* and the bar indicates that it is not true. Then in the earlier example, the C_1 concept would be "redness" and the C_2 concept "squareness." Of course, not all cases with more than three values are composed of independent concepts in combination as in this example. For instance, a color dimension could be partitioned into four concepts: "redness," "greenness," "blueness," and "other colors."

Most experiments in concept learning have involved affirmative, conjunctive, or disjunctive logical relationships. Usually no more than three to five dimensions and three to four values on a dimension are presented. Naturally, the size of the universe of objects depends on the experimental procedure. In some relatively easy procedures, more complex stimuli are presented. Also, ever since the earlier studies, most concept-learning studies have used dimensions that the subject could clearly differentiate and name. The exceptions are verbal mediating studies and some studies dealing with generalization across stimuli.

Further Points about the Definition of a Concept

Few attempts have been made to define precisely what a concept is or even how psychologists use the term (see Kendler, 1964; Archer, 1966). Our earlier definition of stimuli suitable for concept-learning experiments provides a good operational beginning, but it does not satisfy all experimental procedures. One difficulty in defining concept learning is that various experimentalists have used various procedures that are not easily organized according to a simple principle; that is, it is hard to induce the criterial attributes used by different experimentalists. Our solution here will be to follow Hunt and Hovland (1961) by first defining what we mean by a concept and concept learning, then, on the basis of our definition, discussing studies that meet the definition and excluding those that do not.

When first asked what a concept is, the layman replies by giving examples such as "infinity," "love," "communism," "force," and so on. When pressed, the individual can usually distinguish between examples of the concept and the concept itself. A name usually implies a set of anything: objects, symbols, descriptions, attributes. The concept that the layman is trying to express when he gives an example is related to the meaning, the defining characteristics, the necessary and

sufficient conditions that are usually evoked by the example. Hunt discusses Church's idea (1958) about the distinction between the denotation of a name and the "concept of a name." The concept of a name is a statement or classification rule about the conditions that must be met before an entity can be called by or given a name. The denotation of a name is the class of things that can be given the name. Before classification rules can be applied, the set of dimensions over which all objects denoted by the name can vary must be specified. Let this set of dimensions be called E. Then, the classification rule is a function with its arguments the set E and its range a binary outcome, that is, something is an example of the concept or it is not. The set of dimensions E and the values on each dimension of E determine the descriptive space. The concept determines the partition of the descriptive space into those items that do and do not meet the definition.

Now we can see why there is difficulty in clarifying the "concept" of, say, "love." Who can state the dimensions and the values on the dimensions necessary to define it? At this point, the student may feel that the crucial issue has simply been avoided, but the truth is that the definition of most "verbal concepts" such as "love" is beyond our scope. Nonetheless, there are some advantages to a scheme thus limited. A concept can be defined without reference to the set of objects that it denotes. The set of objects can be null (for example, imaginary concepts) or infinite (for example, points on a line). The set of objects is not the concept; thus, just because two concepts have the same denotation does not imply that they are the same concept. If exactly the same set of dimensions E is involved and all objects are possible, then two concepts with the same denotation are equivalent.

Hunt raises another important question. Does the definition given here allow us to use names as we ordinarily do? Hunt mentions two criteria discussed by Suppes (1957) for the use of symbols in sentences: eliminability and noncreativity. A name is eliminable if, when it occurs, it can be replaced by the concept of the name. A name is noncreative if any object to which the name applies can be substituted for the name. These criteria are met if the classification rule defines exactly the same set of objects in the universe as does the name. Say that the name can be applied to the set A and the classification rule defines a set B. Then, $A \subset B$ (A is contained in B), or $B \subset A$ (B is contained in A), or they simply overlap with unique objects in A and B. Only when A is equivalent to B will the use of the name be correct.

Certain uses of the word "concept" are not met by this definition. For example, scientific concepts (such as the concept of gravity) are not classification rules by which names are associated with sets of objects. Instead they seem to be explanatory principles. Piaget's work consists more of explanatory concepts than of studies of the classification concepts defined here.

Concept Learning

Perceptual and conceptual distinction Although it is true that no situation recurs identically for any human at any time in his life, it is the constancy and order of his existence that allow an individual to make categorizations. Bruner, Goodnow, and Austin (1956) have investigated the response categories of identity and equivalence. Identity categories comprise that class of objects that are responded to as being identical. Equivalence categories comprise the class of objects that are discriminable but to which the same response is made. From the immediately obvious equivalence response "It's an apple" to the highly sophisticated classification behavior of a geologist specifying the composition of a rock sample, there is a continuum of categorization behavior. Perhaps arbitrarily, perhaps on the basis of some intuitive psychological knowledge, this continuum has been divided into *conceptual behavior* and *perceptual behavior*. Although Hunt (1962) does not include perception in his defini-

tion of concept learning, Bruner et al. do. Hunt's definition of the difference is about the same as that of Bruner. According to Hunt, (1) perception is immediate, whereas conceptual behavior is more derived; (2) there is no statable rule for perceptual responses, but conceptual responses must have a rule; (3) there is no "set" to categorize perceptually, but conceptual behavior usually requires a "set" to classify; and (4) the perceptual response depends on the stimulus object and also context, whereas the conceptual response must be independent of context. Undoubtedly, there are ambiguous cases. Many conceptual responses become nearly perceptual with practice. For example, many a beginning student of German has difficulty with the Gothic uppercase letters and has to remind himself regularly, for example, that it is "G" that has a vertical stroke coming down from the top. But after a semester's practice, he responds to 𝔊 automatically. Generally, in concept learning, the set of stimuli and the rule determining the concept to be learned are not perceptually determined. However, as the conceptual behavior of young children is studied more thoroughly, this division may have to be revised. Young children do not have the concept of number nor do they categorize in the same manner as older children. Thus, much of the "acquisition or utilization, or both, of a common response to dissimilar stimuli" (Kendler, 1961) performed by young children involves situations that might be classified as perceptual by Hunt.

Attainment and formation distinction The term "learning" or "acquisition" raises another distinction that must be made in order to define conceptual behavior. In general, concept learning refers to the learning of "identified" concepts (Archer, 1966). It is generally assumed that the subject knows the rules and attributes by which the stimuli can be classified, but he does not know which rule and/or attribute is used. Bruner et al. define concept attainment as the process of "seeking defining attributes that will distinguish exemplars" of two given classes. In contrast, they define concept formation as the determination of some meaningful set of categories into which a set of objects may be classified. The important distinction between attainment and formation is whether a partition exists as it does in concept attainment or whether the subject is to form the partition himself. Again, however, with young children, these distinctions are not so easily made. Even if one feels that a child knows what a conjunctive concept is, the child may not be able to utilize it in some simple concept-attainment task where it defines the categorization.

There appear to be three aspects to learning concepts: First, when the subject does not know the specification of the dimension upon which the stimuli can vary, he has to experience a number of stimuli before he can be expected to form a hypothesis. Second, the rule of relationship between values that define the partition of the objects must be one that the subject knows or else it must be "formed" as part of the task. Third, if the dimensions and their values are known, and if the possible rules are known, the subject must select the rule(s) and dimension(s) that define the concept (see Haygood & Bourne, 1965).

Deterministic and probabilistic distinction Not all classification schemes are deterministic. Often a set of stimuli or objects are associated with two different categories on some probabilistic basis. Hunt excludes nondeterministic categorizations, but Bruner et al. deal extensively with them. (The treatment by Bruner et al. overlaps the material on probability learning and is therefore relevant to both probability learning and concept learning. However, because most of the experimental material that has been called "concept learning" has been deterministic, the probabilistic concept-learning cases are omitted here.)

Verbal and behavioral distinction Hunt (1962) makes one further requirement that

may seem restrictive and that eliminates much of the behavioristically oriented research on concept learning. He requires that "the subject must, conceivably, be able to instruct a human to apply the classification rule. The subject is not allowed to use examples during the course of this instruction." This precludes all animal "concept learning" but allows inclusion of machine or computer concept-learning programs. Hunt makes this restriction because he wishes to limit concept learning to situations where the subject has learned a classification rule. This is an important point and introduces another aspect of the definition of concept learning with which most experimental psychologists would concur. Once a subject has learned to classify a set of objects, what has the subject learned? If he has learned specific associations to each of the stimuli, this is generally not considered concept learning. Concept learning requires that a subject learn a rule, a generalizable response habit, a mediated response, or some hypothetical abstract response system so that, on transfer tests with new stimuli, previous learning can be demonstrated to yield positive or negative transfer. The transfer test ordinarily consists of the presentation of a stimulus that has not been presented before but that contains dimensions relevant to the concept.

Let us summarize our definition of concept learning and then apply it to some experimental studies. Concept learning is learning to apply a label to a set of stimuli that vary in a number of ways but that have some common aspect which determines the correct classification of the stimuli. Although the demarcation line between perception and conception cannot be precisely located, perceptual learning is in general to be excluded. Although various distinctions between concept "attainment" and "formation" have been made, it might be better to make a four-way specification: (1) discovering the rules of classification, (2) discovering the dimensions used in classification, (3) learning the rules used in classification, and (4) learning the dimensions used in classification. The latter two are usually assumed or spelled out to the subject except when children are involved; the former two historically have not been clearly separated, but they constitute the problem for the subject. The concept learned must be transferable or statable so that we can be sure that a rule and not just a set of associations has been learned.

Early Concept-Learning Studies

Before we proceed with basic paradigms and theoretical developments in concept learning, we should apply our definition of concept learning to some early studies. Hull (1920) presented subjects with 12 sets of pseudo-Chinese ideograms to be classified on the basis of unique radicals (see Chapter 17, p. 785). A set consisted of 12 ideograms, each with its own radical. After a subject had learned one set to a criterion, he was presented with the next set, which contained the same 12 radicals, but embedded in different ideograms. Certainly, learning the first set was not concept learning because the subject could not determine the criteria to classify each stimulus. In fact he might have learned the ideogram on the basis of the wrong cues, for each ideogram was a compound of cues. When the second set was presented, the percentage correct on the first trial jumped from chance to 27 percent, then to 38, 47, 55, and 56 percent on sets 3, 4, 5, and 6, respectively. (See Woodworth and Schlosberg [1954] for a more complete presentation.) Thus, Hull's experiment is primarily a discrimination task with common and changing cues, and it only partially meets the criteria of concept learning. It is not really perceptual, though more so than is common in current concept-learning studies. Transfer occurs, but, what is more important, the subject is not trying to discover the rule of classification in the situation: The ideograms lack easily specified dimensions and values. Thus, relationships between values are impossible. Although the task does not conform to our ideal experimental definition, the experiment is

important because it illustrates that discrimination learning and concept learning are on a continuum. Forcing polarization is experimentally and analytically useful, but the area in between the extremes must also be handled. Even when only common elements are involved, many researchers feel that the subject is using a rule. If the criterion was always invoked that the concept-learning experiment be more than association of common elements, many of the experiments intended to investigate concept learning would have to be called "discrimination experiments." Certainly, in particular, the simple affirmative concept experiment differs little from a classical discrimination experiment (see p. 924).

Smoke (1932) dealt with stimuli that had to be sorted on the basis of common perceptual structures or patterns. Instead of always presenting the same physical stimulus, he always presented the same relationship. For example, this relationship might be based on whether there were two dots in a figure or only one dot—but the position of the dots could be varied. The stimuli were identical only in that the subject already had an equivalence class for the various physical examples presented. Such an equivalence class might be a perceptual response, a categorizing response, or a mediational response (that is, an association common to all examples). Smoke introduced the rule explicitly for his subjects. "Let us suppose the concept is 'zum' and may be defined thus: 'three straight red lines, two of which intersect the third, thereby trisecting it.' " In line with later concept-learning research, the subjects were told explicitly to look for the rule defining, say, a *tov*. However, Smoke noted that many subjects performed correctly but could not verbalize the hypothesis correctly. Thus, Hunt's criterion of verbalization was not fulfilled.

On each of a series of trials, Reed (1946a, b, c) presented the subjects with a different set of four words. Each set had to be classified with a nonsense syllable. In each set of four words, one word defined the category to which the set belonged. For example, one set for KUN was (*horn-leaf-monkey-debt*), and a second set for KUN was (*fame-ought-tiger-saucer*). The common concept is presumably "animal." Initially, the subject had to make the correct associative response, but once a few examples had been presented and associated with the same response, the list could easily be searched and classified. Reed found that increasing the length of the list did not increase the learning difficulty. He informed some of his subjects that each nonsense syllable defined a class of similar things; these subjects learned faster than others. In contrast, subjects who looked for association rules based on the first letters of the words were slower to learn. There was very little forgetting over days, and in all ways the learning in this task was superior to paired-associate learning of a list of equivalent length. Our definition of a stimulus may seem to have left out the crucial element in Reed's experiments, namely, the classification by the association made to a set of words. However, for such stimuli as Reed's, the dimensions must be defined in terms of the subject's associations to the words and not in terms of the physical characteristics or even the defining characteristics of the word. Certainly, there would have been many individual differences, and many dimensions considered by the subject would have been irrelevant. Also, of course, there is the likelihood that different examples might have elicited the same classification word. The important point is that the dimensions according to which the concepts were defined were not presented in the stimulus itself but consisted of fairly well learned associations that subjects had to the words. The fact that the dimensions need not be physically present in the stimulus adds a new level of complexity to concept learning. See the discussion of Greeno and Scandura (1966) on page 1007 for a recent analysis of this experimental procedure.

Heidbreder's thesis (1947), derived from Gestalt psychology, was that cognitive reactions could be ordered. For example, the perception of concrete objects should be

the easiest and most dominant, whereas spatial forms should be less likely to be noticed, but still easier than abstract ideas such as number. She presented a list of pictures to subjects in a paired-associate procedure. After the list was learned, a new list was introduced containing objects that could be classified in exactly the same way as the items on the previous list. Examples of the pictures are: 5 glasses, 5 spoons, 5 letters, and so on; a Greek building, a cabin, a church, a simple house, and so on. Eventually, the subjects would respond correctly to an item the first time it was presented, illustrating that some mediating response was taking place.

Heidbreder's experiments were similar to Reed's in that the dimension of categorization was provided by the subject's response to the stimuli. Such responses provided by the subject are usually called *mediating responses.*

The early experiments in concept learning just discussed were not sufficiently well controlled to allow definitive analysis. One problem was the complexity of the stimulus material and the subjects' idiosyncratic reaction to it. A second problem was inexact instructions, which resulted in a poor definition of the task for the subjects. From the late 1940s to the present day, the trend has been toward giving clearer instructions, more carefully structured stimuli, and maintaining more control over the presentation procedure. With these changes have come more precise theories and a refinement of what is meant by concept learning.

Procedures in Concept Learning

The most common procedure for testing concept learning is derived from discrimination experiments. In the usual discrimination experiment, two stimuli are presented successively or simultaneously with position randomized. However, in concept-learning experiments, more than two different stimuli must be presented, so these are randomized and presented one after the other until the list is exhausted. Then the stimuli are randomized once more and presented again. If the set of stimuli is large (for example, five 4-valued dimensions yield 1024 stimuli), then usually only a sample is selected and presented. On each trial, the subject makes a classification response such as "yes" (it is an exemplar of the concept) or "no" (it is not an exemplar of the concept). Although it is not necessary, and indeed is sometimes impossible, the stimuli are ordinarily divided into two classes. When more categories are defined, the problem can be regarded as a multiple concept-learning problem, or a problem with multiple categories related to the concept. Still following the discrimination paradigm, many studies present two stimuli simultaneously. In such cases, the two stimuli usually differ on all dimensions; that is, they are complementary. If this were not the case, the subject could eliminate dimensions with the same value on both stimuli if one of the stimuli were always correct and the other always wrong.

Of course, the experimenter can present more than two stimuli at a time. Bruner et al. (1956) presented the total set of stimuli but at the same time varied the standard procedure. First, the experimenter presented a stimulus and stated that it was or was not an example of the concept. Then, instead of asking the subject to decide whether or not another stimulus was an example of the concept, the subject himself picked the next stimulus and was informed by the experimenter whether or not it was an example of the concept. At each choice point, the subject could state the rule he thought was operating. Subjects were told to make as few choices as possible in determining the conjunctive concept. When more stimuli are presented, the questions arise as to how much information the subject gets before he must make a choice, and, if the choices are serial, whether the procedure differs from ordinary successive procedure. Possible variations of this procedure include ordering or scrambling the stimulus cards and replacing or separating selected cards according to their

classification. Such variations have not been thoroughly investigated.

Another procedure frequently employed is the card-sorting task, usually used with the Wisconsin Card Sorting Stimuli. The stimulus deck consists of four values on each of three dimensions: color, form, and number. The subject is first given four cards to start the piles—single red triangle, two green stars, three yellow crosses, and four blue circles. Then the subject is instructed to sort the remaining cards into four categories. The procedure normally involves changing the correct sorting rule after one rule has been learned.

Theoretical Analysis

Early theoretical work treated concept learning as an extension of discrimination learning. The minimum condition for concept learning is the ability to distinguish between a set of common cues or attributes that define the concept and all other cues with which the common cues might occur. However, the simple treatment of discriminative processes by SLT is inadequate for describing the perfect discrimination that usually occurs: Attainment of a concept is certainly evidence for perfect discrimination. Hence to handle even the minimum requirements of concept learning, a better model of discrimination learning is needed. During the late 1950s, a number of approaches were developed in attempts to solve the problem of overlapping cues in discrimination. Some of these approaches have been extended to concept learning.

Observing responses A fairly natural extension is simply to note that animals and humans do not take in all the cues of a situation at once. Although SLT handled separate manipulatable cues by assuming different sets of elements for each cue, these cues were controlled by the experimenter. When they were presented, the subject was assumed to observe or sample them. But a subject can either orient toward specific cues or attend to them differently, according to their utility in a situation. Atkinson (1960) and Wyckoff (1952) developed models that assumed that subjects learned orienting responses. If a subject oriented toward relevant cues, he would ignore the irrelevant ones. An observing response is usually considered a physical response, probably measurable in principle. An extension of this idea is the attentional response, which is usually considered more "abstract" or "perceptual" than the observing response. Many have argued that there is a definite difference between an observing response and an attentional response, but sharp theoretical distinctions have not been established. Perhaps the clearest statement would be that an observing response involves muscular changes which orient the subject's senses so that they respond to specific cues, whereas an attentional response involves some central mechanism, presumably not muscular, which selects specific cues after they are received. Operationally, the distinction seems to be that an observing response is directly measurable but an attentional response is only inferred.

Adaptation of cues A second approach, equivalent in many ways to that of the observing response, is to assume that irrelevant or common cues become inhibited or adapted; that is, they diminish in their probability of being sampled over trials. Bush and Mosteller (1951) and Restle (1957) introduced this idea into their formal models. However, neither the idea of the observing response nor that of adaptation of cues can handle discriminative situations involving patterns or concept-learning situations involving disjunctive concepts. Another problem with the idea of adaptation of cues is that of "unadapting" them. In successive reversals of concepts, subjects get better and better, a phenomenon difficult to predict if it is assumed that cues are alternately being adapted and unadapted (Gormezano & Abraham, 1961).

Mediational responses Another suggested solution to the problem of overlapping stimuli is Goss's *mediational response anal-*

ysis (1961), which assumes that a second response is associated with each component or cue of the stimulus. This association is either one previously conditioned or a generalization from some previously conditioned association. Mediational analysis has been particularly useful with verbal hypotheses such as those represented by the Reed and Heidbreder studies. Reversal-shift studies have also relied heavily on mediational analysis of their results. Although a mediational response, or some equivalent abstraction from the stimulus, is required to handle concept learning, there is still a question as to whether it is sufficient. Hunt (1962) feels that it is not, arguing that mediational theory is not stated rigorously enough. However, with a rigorous statement of the axioms, the predictive power of the mediational extension of S-R formulations is weakened. Another problem with mediational theory is that there are various views as to what constitutes a mediational response. These alternative views must be better defined and put to a systematic test before further quantitative work can be done. Conceivably, all variations could be correct, but if so, the theory must be made to state when each is appropriate. Most tests of mediational theory have been qualitative. The only quantitative theoretical development has not always been correct (Popper, 1959). (For further discussion, see Jenkins, 1963; Mandler, 1961, 1963, 1967.)

Quantitative theories Another class of theories must be mentioned, although it includes primarily theories of discrimination. Zeaman and House (1963) and House and Zeaman (1963) have developed theories of attentional processes in retardates. Although their work has dealt mostly with the discriminative reversal situation, many of their ideas have supported and inspired the trend toward quantitative work in discrimination learning and concept learning.

The first quantitative theory of concept learning was developed by Bourne and Restle, following an earlier theory of discrimination learning developed by Restle (1955a, b, 1957). The Bourne and Restle theory (1959) was one of cue conditioning in which overlapping cues adapt out. Five processes within concept learning were very successfully handled: (1) the role of redundant relevant cues, (2) the analysis of two-choice problems and the extension to four-choice problems in which two dimensions were simultaneously relevant, (3) the additivity of irrelevant cues, (4) the effects of delaying reinforcement, and (5) the effects of omitting feedback on some trials. We consider here a later theory by Restle (1962) and a modified version of it by Bower and Trabasso (1964) that do not have the drawback of a model with adaptation of irrelevant cues. These two theories also incorporate some of the newer ideas concerning concept learning by assuming that subjects test hypotheses.

Hypothesis- or Cue-Selection Models

In his original development of the all-or-none concept-learning model, Restle (1962) emphasized that in cue-learning studies (discrimination learning and concept learning), the subject's task is not to form associations between stimuli and responses, but to select the association intended by the experimenter. The response itself and the discrimination of the stimuli along various dimensions are all within the capacity of the subject when the problem starts. The suggestion is made that concept learning is not so much an association process as a selection process. But what is selected? Restle assumes that the subject selects strategies or hypotheses that are particular patterns of responding to stimuli. Examples are "win-stay lose-shift" or "alternate" or "respond to the red stimulus." In Bower and Trabasso's cue-selection model (1964), in contrast, the main behavioral process is the selection of relevant stimulus attributes rather than the selection of strategies. They assume that the subject first encodes the stimulus. Encoding is a process of answering questions about stimuli; for example, How many objects? What color? What shape? These attending responses are like observing responses or attentional responses but are usually not observable. Certain qualities of the

coding response assumed by Bower and Trabasso are important: It can be influenced by learning, as is illustrated in the reversal and dimensional-shift experiments that show negative transfer effects presumably due to attention to one stimulus aspect. It can be rapidly changed by instructions and set. In contrast to Restle's hypothesis model, the cue-selection model has two sets of habits to be learned. One is the attentional response, the other the association of the response to the attributes on the dimension attended to. Such a breakdown has one advantage. In concept-learning problems or discrimination problems in which multiple responses are associated with multiple values on a single dimension, solving the problem also requires paired-associate learning. When the problem involves only two values (say, red is a 1; green is a 2), the paired-associate learning is almost immediate, but if, say, five colors and five responses are involved, the process will take at least a few trials. Restle puts such associations into the strategy itself. Aside from this difference in the qualitative abstract way of looking at the problem, the theories of Restle and of Bower and Trabasso are nearly identical. (See the discussion of Restle's theory for paired-associate learning on page 1005.

Hypotheses Restle assumes that a subject has a population of hypotheses that includes three types of hypotheses: (1) relevant or correct hypotheses, (2) irrelevant hypotheses that are correct with a probability of .5, and (3) wrong hypotheses that are never correct. He labels these C, I, and W; $C + I + W = H$, the total set of hypotheses. The theory has three possible sampling rules: (a) A subject can select one hypothesis on each trial, (b) the subject can select more than one hypothesis but less than H, or (c) the subject can select all H hypotheses. When the subject considers all strategies at once, it is assumed that, on each trial, he decides on a response and eliminates hypotheses not in agreement with it. Restle postulates that the subject eliminates hypotheses because he has only a finite memory. A similar process is assumed when the subject considers only a few hypotheses at once. Once the subject has selected the correct hypothesis, he will make no more mistakes. Until he does discover the correct hypothesis, however, he is selecting mostly from the I hypotheses, which produce correct responses with a .5 probability. The W hypothesis produces an error immediately, but W hypotheses are assumed to be infrequent because they must be complementary to the correct hypothesis. Also, they produce an error and thus are not maintained for more than one trial. Subjects respond at approximately a chance level until the correct hypothesis is selected. From that trial on, they respond correctly. The trial on which they select the correct hypothesis is a random variable depending on the proportion of correct hypotheses in the population of hypotheses. Note that this differs from SLT in that, besides hypotheses in the place of elements, the learning rate here depends on the initial proportion of correct hypotheses and not on the sampling probability. An important result of Restle's analysis is that the sample size does not change the learning rate at all.

Cues Let us now introduce the theory as developed by Bower and Trabasso (1964), who have given it the structure of a Markov chain. The axioms of the theory follow.

1. *Psychological States.* There are three states: S is the correct state when the subject has selected the correct dimension and his responses are conditioned correctly to the various values on the dimension. E is the error state when the subject has not selected the correct dimension and his response is wrong. C is the correct state when the subject has not selected the correct dimension, but when his response is correct.

2. *Initial State Probabilities.* On trial 1, subjects enter states S, E, and C with probabilities 0, q, and p, respectively, $p + q = 1$. Probability p is the probability of guessing correctly; it is determined by the stimulus conditions and response conditions of the

experiment. With simple binary-valued dimensions and affirmative concept rules, $p = q = .5$ can be assumed. However, as values increase and categories of classification increase, p should decrease. Also, specific presentation schedules may change the p values.

3. *Transition Probabilities.* The probabilities that the subject will make a transition from any state to another state on a given trial are determined by the effect of information feedback on every trial, by the stimulus dimension to which the subject is attending, and by the stimulus presented by the experimenter. These transitions are represented in the matrix **T**:

$$\mathbf{T} = \begin{array}{c c|c c c c} & & \multicolumn{3}{c}{\text{Trial } n+1} & \\ & & S & E & C & P(\text{Correct Response}) \\ \hline & S & 1.0 & 0 & 0 & 1.0 \\ \text{Trial } n & E & e & q(1-e) & p(1-e) & 0.0 \\ & C & 0 & q & p & 1.0 \end{array} \qquad (46)$$

The parameter e is the probability that the subject will select the correct dimension and that the appropriate response will be conditioned. This parameter is assumed to remain constant throughout the experiment. Because 2-valued dimensions are assumed in this model, there is no state to represent correct selection without all responses being correctly conditioned. With only two values, conditioning of either response implies conditioning of the other. Note that, once the correct dimension has been selected and the response conditioned, no transitions take place. A state such as S is known as an *absorbing state.* Also note that learning occurs only on error trials, that is, from state E. Whereas justification for this assumption is originally empirical (Bower & Trabasso, 1964), the psychological interpretation is that only on error trials do subjects consider trying a new dimension. On correct trials, they stay with the dimension or hypothesis that led to the correct response. The same argument justifies making state S an absorbing state.

Markov chain The three axioms just presented define a Markov-chain process. A Markov chain is a special kind of stochastic process in which the transitions between states depend only on the state that the process is in on the trial immediately before the transition, and not on any earlier states that may have been entered. Thus, if a subject passed through states *CCCCCCCCCCE* on trials 1 through 11 and another subject passed through states *EEEEEEEEEEE* on trials 1 through 11, according to the theory they would both have the same probabilities of a transition to S, E, or C: e, $q(1 - e)$, and $p(1 - e)$, respectively. In other words, a transition from E to S, when learning occurs, is independent of the number of trials preceding the entry into state E, the number of correct responses, and the number of error responses. This important implication of the theory leads to a number of statistical tests designed to test the implication directly (Suppes & Ginsberg, 1963).

Stationarity The subject selects the correct dimension on an error trial—the trial of the last error L. (The trials before L are called the *presolution trials.*) Before this last error, he responds at chance with p = probability of a correct response and q = probability of an error. These probabilities do not change over trials and are independent from trial to trial. A process known as *Bernoulli trials* is defined in exactly this way. It is analogous to flipping a biased coin with p = probability of heads for L trials. A chi-square test to see if the response proportions are stationary before the last trial can be set up. For each trial or block of trials before the last error, we can determine the frequency of correct re-

sponses and error responses. On each successive trial or trial block, the number of cases will decrease because subjects are excluded on their last error. The overall proportion of correct responses over all trials and subjects yields an estimate of p from which the theoretical expectations can be computed. A chi-square goodness-of-fit test is then appropriate.

Independence Another implication of the model concerning presolution trials is that errors are independent from trial n to trial $n+1$; that is, $P(\text{Err} \mid \text{Cor}) = P(\text{Err})$ and $P(\text{Cor} \mid \text{Err}) = P(\text{Cor})$, where "Err" and "Cor" stand for "error" and "correct," respectively. A chi-square test is again appropriate. Let $f_{i,j}$ = frequency of trials on which an i response occurs on trial n and a j response on trial $n+1$, where i and j = Err or Cor. These four frequencies form a 2×2 contingency table, which is appropriately tested by a chi-square test.

The previous stationarity test could be erroneously nonsignificant if individual subjects' proportions changed over trials (see the discussion of averaging in the section on probability learning). However, other tests to see if the presolution trials are Bernoulli trials can easily be devised. Suppes and Ginsberg (1963) mention a test based on expected binomial distribution. Another reasonable procedure is to form a Vincent curve on the response sequences made before trial L. Say that a blocking factor of four is chosen. Then each sequence of error and correct responses before L is divided into four equal parts. The errors in each of these four parts are added across subjects. The first block represents the first fourth of the presolution responses for each subject; the second block the second fourth of each subject's presolution responses, and so on. These various blocks should have equal proportions of error responses. Without knowledge of the underlying function, the Vincent technique can lead to unknown functions, but in this case the simplicity of the assumed function makes the test quite legitimate. A simple variation of this technique is to take for each subject the proportion of errors in the first half and second half of the presolution trials and run a t-test on the difference between these two proportions to test whether or not individual subjects change over trials.

Statistics of the model We derive two statistics of the model: the distribution of the total number of errors and the distribution of the trial of the last error. Most other statistics are simple tests of the Bernoulli assumption for presolution trials.

Total number of errors. Because the subject can learn only on error trials, one simple observation makes this derivation quite easy. The correct trials can occur with any frequency or density across trials without changing the expected number of errors. Consider a subject who makes an error on any trial. The subject then selects the correct dimension with probability e or he does not with probability (1 − e). If he does select the correct dimension, he makes a transition to state S where no more errors are made. Thus, the probability of one error is e because at least one more error must occur if a transition to S did not occur. The probability of making two errors is (1 − e)e; the first error does not lead to a transition to S, but the next error does. The probability of making three errors is (1 − e) (1 − e)e. The pattern is now clear: Let T be the total number of errors; then,

$$P(T = k) = e(1 - e)^{k-1} \tag{47}$$

This is a simple exponential function with asymptote zero. The expectation of T, $E(T)$, is defined as the first moment and is computed by weighting each value of T by its probability.

$$E(T) = \sum_{k=1}^{\infty} ke(1 - e)^{k-1}$$

The solution to this sum is

$$E(T) = \frac{1}{e} \tag{48a}$$

The variance of the distribution is defined as $E[T - E(T)]^2$. By simple algebraic manipula-

tions it can be written $E(T^2) - [E(T)]^2$. The $E(T^2)$ is

$$E(T^2) = \frac{1}{e^2}$$

and the variance becomes

$$\text{Var}\ (T) = \frac{(1 - e)}{e^2} \qquad (48b)$$

Trial of the last error. Let L designate the trial of the last error. In order for any trial k to be the trial of the last error, an error must occur on that trial and selection of the correct dimensions must also occur. Given that the subject is not in state S, the probability of both an error and conditioning is qe. But what is the probability that a transition to S has not occurred before trial k? The probability that a transition to S does not occur is $p + q(1 - e) = 1 - qe$. The probability that a transition to S does not occur for $k - 1$ trials is $(1 - qe)^{k-1}$. Thus the probability that k is the trial of the last error is

$$P(L = k) = qe(1 - qe)^{k-1} \qquad (49)$$

The expectation and variance are easily derived. Note, for instance, that if e is substituted for qe, exactly the same function occurs for L as for T.

$$E(L) = \frac{1}{qe} \qquad (50a)$$

and

$$\text{Var}\ (L) = \frac{(1 - qe)}{(qe)^2} \qquad (50b)$$

A simple relationship exists between $E(T)$ and $E(L)$:

$$E(T) = qE(L) \qquad (51)$$

If q, the probability of an error, $= .5$, as in binary-valued dimensions classified into two categories, then there should be one-half as many errors as trials before the last error.

The value $E(T)$ can be used to estimate the parameter e, and the presolution proportion of correct responses can be used to estimate p. When these parameters are known, the model can predict the distributions just presented and their variances, as well as other statistics such as runs of errors, trials until the first success, and autocorrelation of errors with different lags. If the experiment is large enough and is carefully run, such a wealth of statistics will almost certainly ensure finding any lack of correspondence between the model and the data. Bower and Trabasso (1964) present the derivation of these other statistics; an elementary but complete treatment of the model itself can be found in Atkinson, Bower, and Crothers (1965).

The correspondence between *e* and the stimulus set When we introduced Restle's idea of a pool of three different types of hypotheses, C, I, and W, we implied that the learning rate is a function of the ratio of relevant cues to the total number of cues. Further, p is determined by $(C + .5I)/(C + W + I)$. Bower and Trabasso also assume that e and p are functions of the stimuli and associate with each stimulus dimension a weight reflecting the attentional value of the attribute. Let w_i be the combined weight of all irrelevant cues, and w_r the combined weight of all relevant cues. Then the probability that the subject selects a relevant dimension is

$$r = \frac{w_r}{w_r + w_i} \qquad (52)$$

Given that the dimension is selected, the cue is conditioned with probability θ, and the effective learning rate e is $e = r\theta$. Bower and Trabasso assume that the conditioning process goes on even for irrelevant dimensions, an assumption that allows a prediction apparently not allowed by Restle's version of the model. The prediction is that if an irrelevant cue is partially redundant (that is, if it correlates with the relevant cue above a chance level), the subjects will sometimes select this redundant cue and condition it before making a transition to the S state. Such conditioning will reflect the level of redundancy, and on future tests subjects should show a kind of probability learning. For example, if the rele-

vant dimension were color and a red triangle occurred on 75 percent of the "red" trials, then the subjects' responses to a triangle alone (color being omitted) should be biased toward the response associated with the color red. Results supporting this assumption have been reported by Binder and Feldman (1960).

The assumption that the learning rate or selection probability depends on the weights of the cues leads to some very important tests of the theory. By evaluating the various weights of dimensions with independent groups of subjects, a priori predictions can be made about the learning rate of new groups and groups with combined cues. An example will show how the theory allows such predictions. Assume that three different groups are tested. One group learns on dimension 1, the second on dimension 2, and the third can learn on either dimension. The third group has redundant cues, which means that the values on dimension 1 and dimension 2 are perfectly correlated; that is, for example, value 1 on dimension 1 is always combined with value 1 on dimension 2. Let the weights of the two dimensions be w_1 and w_2. Then the learning rates for the three groups are

$$(1)\ e_1 = \frac{\theta w_1}{w_1 + w_2 + w_i}$$

$$(2)\ e_2 = \frac{\theta w_2}{w_1 + w_2 + w_i}$$

$$(3)\ e_3 = \frac{\theta (w_1 + w_2)}{w_1 + w_2 + w_i} = e_1 + e_2$$

Note that the third group should have a learning rate equal to the sum of the learning rates for the two other groups, and thus the number of errors for the third group, T_3, can be derived from Equation 47.

$$T_3 = \frac{T_1 T_2}{T_1 + T_2}$$

Evaluation of the Cue-Selection Model

Three assumptions of the cue-selection model require verification. One is the sudden, all-or-none learning assumed to occur when the correct dimension or attribute is selected. A corollary to this axiom is that, prior to the trial on which learning occurs, there is no change in the probability of a correct response. On the other hand, subjects might learn a few stimuli by rote association. The responses to these stimuli would then be correct and would change the probability of a correct response before the trial of the last error. A second assumption is that the learning rate remains constant over trials. However, it is possible that subjects might continue to guess at a chance level (that is, at the *p* level) even though they are learning about relevant and irrelevant hypotheses. By eliminating dimensions when they find them wrong, subjects could eventually learn the correct hypothesis and begin to select from a smaller set of dimensions. This would make the learning parameter e change over trials. The third assumption is that cues are additive. However, if subjects selected cues systematically rather than at random according to their weights, w_i, the cues would not be additive.

Concept reversals Bower and Trabasso (1963) have run a study to test the constancy of the parameter e. The crucial aspect of the design was borrowed from the earlier continuity-noncontinuity studies in discrimination learning (Krechevsky, 1932; McCulloch & Pratt, 1934). Subjects are trained on the wrong hypothesis for a number of trials and then are switched to the correct response assignments. Whatever was learned during the presolution trials should retard later learning. Bower and Trabasso found no evidence in support of these assumptions for partial learning of relevant cues or for elimination of irrelevant cues for two different problems varying in difficulty. Other aspects of the data were extremely well described by the cue-selection model. In another experiment, Bower and Trabasso switched the response assignments of one group between two dimensions (successive dimensional shifts, SDS) after every second error. The subjects were

informed of the first error, but if and when they made another error, the experimenter told them they were correct and immediately switched to the other response assignment. The SDS group was compared with the average of two other groups that learned the two relevant dimensions without switches. Bower and Trabasso found no difference between the averages, presumably because, on the average, subjects learned with one or the other dimension. They concluded that, after an error, subjects select dimensions randomly, including the dimension just rejected.

Of course these results supporting the theory are not independent of procedural variables. We may conclude that, while the simple all-or-none cue-selection model cannot handle all concept learning, it does quite well with concept learning in which the stimuli are complex and presented rapidly, and in which subjects are given a "set" to look for the relevant dimensions in simple affirmative concepts.

Extended training In those studies of concept learning that have been well described by the cue-selection model, subjects have generally been given only a simple preliminary practice problem and explicit instructions. However, Millward (1968) ran an experiment in which each subject learned 120 affirmative concept-learning problems. The four stimuli for each problem consisted of combinations of two shapes and two colors selected from eight shapes and colors for each problem. The cue-selection model quite adequately handled the results of the first problem; for example, the trial of the last error was almost exactly twice the total number of errors. However, if repeated problems are given subjects, the model, as defined earlier, becomes inadequate. Two assumptions made in the cue-selection model seem particularly inappropriate with practiced subjects. The first assumption is that subjects always start in either state E or state C. Bower and Trabasso made this assumption primarily because it was empirically called for—subjects rarely learn without making at least one error. However, we would expect that subjects with a great deal of practice on problems in which one of two dimensions was always relevant would begin to select one of these two dimensions on the very first trial. The second questionable assumption is that subjects select dimensions with replacement of the dimension that led to the error. Millward modified the cue-selection model so that subjects could initially select the correct dimension and make no errors at all. After many problems, the parameter measuring the probability of initially selecting the correct dimension was about .45, indicating that subjects selected one of the two dimensions most of the time.

In the cue-selection model, the parameter e is supposedly related to the probability that a subject will select the correct dimension and condition the appropriate response after correct selection. We might assume that, when only two dimensions were ever relevant, subjects would learn to select between these two and, indeed, the initial selection probability indicated that they did. However, e was estimated well above .5: After an error, subjects were not sampling with replacement, but without replacement. After an error they switched to the other dimension with a probability of about .9. With appropriate parameter values, the model can predict optimum performance, and after 100 problems, nearly optimum performance was observed.

Random reinforcements Levine (1962) ran a study in which he showed that only six random reinforcements (RR) produced a decrease in the rate of learning a concept. These results contradicted the predictions of the cue-selection model, but Bower and Trabasso explained the contradictions by the fact that only two dimensions had been used and that subjects probably did learn to eliminate hypotheses. However, Holstein and Premack (1965) ran another random reinforcement study in which six dimensions were employed. Their results supported those of Levine, and they suggested that RR may in fact increase

the pool of hypotheses considered by a subject. Hence, after a certain number of RR trials, learning would tend to be retarded.

Memory factors in cue-selection models Trabasso and Bower (1966) noted that their analysis of the successive dimensional-shift (SDS) procedure was theoretically incorrect. Assume that Group 1 had learned with cue 1 relevant, Group 2 with cue 2 relevant, Group 1–2 with both cue 1 and cue 2 relevant and redundant, and Group SDS with the switching procedure. Trabasso and Bower had assumed earlier that the total number of errors for the SDS group would be equal to $(T_1 + T_2)/2$, where T_i is the total number of errors for Group *i*. However, the correct analysis indicates that the SDS group would learn exactly like a group for which both cue 1 and cue 2 are relevant and redundant (that is, Group 1–2). If $e_1 = w_1/(w_1 + w_2 + w_i)$ and if $e_2 = w_2/(w_1 + w_2 + w_i)$, then $e_{1-2} = (w_1 + w_2)/(w_1 + w_2 + w_i)$ and

$$T_{1-2} = \frac{T_1 T_2}{T_1 + T_2} < \frac{T_1 + T_2}{2}$$

In the SDS procedure, either cue will solve the problem because, if a subject is working with cue 2 and the experimenter is giving reinforcements according to cue 1, the subject will make an error. Then the subject can select cue 1 and make no more errors. Or he can select cue 2 and make a second error. However, after the subject has made the second error, the experimenter does not tell the subject it is an error; the subject does not resample, and the experimenter switches to cue 2, which is now in agreement with the subject's hypothesis. One fact is important here: The experimenter assigns the values of dimension 2 in a way consistent with the subject's responses. Thus, the correct analysis indicates that the SDS procedure should be identical to the Group 1–2 condition with both cues relevant and redundant. Previous results had not indicated that SDS was easier to learn than $(T_1 + T_2)/2$, and another, more reliable, experiment that Trabasso and Bower ran (1966) also failed to show the additivity of cues that the re-analysis had predicted. The SDS group made a mean number of errors less than the average mean number of errors made by Groups 1 and 2, but it still was not equal to $T_1T_2/(T_1 + T_2)$ as predicted.

To handle this empirical discrepancy from the theory, Trabasso and Bower modified the theory by adding a simple memory process, the *memory-cue-selection assumption.* On an error trial, the subject was assumed to (1) remember the stimulus pattern and correct response assignment from the previous trial, (2) compare the stimuli occurring on each trial and eliminate any dimension that was inconsistent, and (3) remember the eliminated dimensions for *k* trials. Memory of inconsistent hypotheses implies that they will not be used for *k* trials. The comparison is made between the stimuli on trial $n - 1$ and the stimuli on the error trial *n*. Any dimension that keeps the same values when different responses are assigned to the two stimuli or any dimension on which the values change when the stimuli are assigned the same response is eliminated. With this assumption added to the cue-selection model, the results of the SDS group were fairly adequately described when stat-subjects were run to test it. (Stat-subjects are simulated subjects that perform as the model specifies; because explicit derivations are difficult to make with this model, Trabasso and Bower had to simulate the model.)

Of perhaps greater interest is the fact that this revision of the model explains Levine's and Holstein and Premack's random-reinforcement results. The effect of random reinforcement is to reinforce the subject inconsistently so that he sets aside a number of dimensions. After about 6 trials, the subject would have had ample opportunity to set aside the relevant dimension. Once this dimension had been set aside and when the experimenter switched to consistent reinforcement, it would take a constant *k* number of trials before the subject would reconsider

the hypothesis previously set aside. These predictions conform exactly to Holstein and Premack's results. Learning was increasingly retarded up to 6 trials of RR, but thereafter the retardation effect of more RR trials was constant. Apparently the simple idea that cues are resampled with replacement is not correct.

The memory version of the Trabasso and Bower cue-selection model (1966) has been questioned by Dodd and Bourne (1967). Three assumptions crucial to the memory-cue-selection model are: (1) hypotheses are changed only on error trials, (2) a new hypothesis is always consistent with the information given on error trials, and (3) a new hypothesis is consistent with information given on the previous trial. Three deductions that can be made from these assumptions were tested by Dodd and Bourne. Consider all the subjects in an SDS procedure who make an informed error, later make an error that is called "correct," and then make no more errors. (1) Between the informed error and the uninformed error, the subjects should respond in a manner consistent with the final correct response assignment—call it the "solution hypothesis." (2) The solution hypothesis should be consistent with the information provided by the last error trial. (3) The solution hypothesis should be consistent with the information provided by the trial immediately preceding the trial of the last error. Dodd and Bourne found instances that violated all three of these deductions. A violation of the first deduction occurs when subjects switch hypotheses on correct trials. Violations of the other two occur when subjects do not efficiently use the information from the error trial and from the trial before the error trial.

Other results Many experiments have yielded generally satisfactory results for the additivity-of-cues assumption made in this theory. Papers by Restle (1955a, b, 1957, 1958, 1959), Bourne and Restle (1959), and Trabasso (1960, 1963) review the literature on additivity of cues very thoroughly.

When the underlying theory is a Markov chain, one way to relate latency as a dependent variable to response proportions is to associate with each state of the Markov chain a latency distribution. Presumably, each state has a latency distribution with its own mean. In the all-or-none model there would be two latency distributions. Millward (1964b) and Suppes, Groen, and Schlag-Rey (1966) provided support for the all-or-none model in studies applying all-or-none Markov chains to paired-associate learning. Latencies seemed to remain stable for trials before the last error and decrease rapidly after the last error. Kintsch (1965) observed similar results for latencies and GSR responses in paired-associate learning. In a similar analysis for concept identification, Erickson, Zajkowski, and Ehmann (1966) found that latencies on correct trials and error trials were not different, that latencies on trials following error trials were longer than latencies on trials following correct trials, and that latencies showed a rapid decrease on trials following the last error. The results of Erickson et al. are consistent with the cue-selection model in that we would not expect latency differences between error and correct trials; rather we would expect longer latencies on a trial after an error when a new hypothesis was selected. In contrast, the decline in latency after the trial of the last error is not exactly in support of the all-or-none theory. We would expect either a sudden decrease in the subject's latency or a change to the latency level for correct responses after a correct response.

In the cue-conditioning model developed by Bourne and Restle (1959), an analysis of four-choice concept-learning problems was made. (A four-choice concept-learning problem is one on which the subject must classify a concept into four categories.) The classification is based on two affirmative rules defined for two independent binary dimensions. For example, if shape and color were the relevant dimensions, the following classifications might be set up: red square = 1, green square = 2, red circle = 3, and green cir-

cle = 4. Bourne and Restle's suggestion that subjects learn two independent problems was confirmed by their results in terms of the mean total number of errors. Trabasso and Bower (1964a) ran a four-choice experiment and analyzed it in detail according to the all-or-none, cue-selection model. Their analysis indicated strongly that the two dimensions were learned independently and that each was learned as an all-or-none process.

Trabasso and Bower's model for the four-choice problem is a three-state Markov chain. State S_0 is assumed to occur when neither subproblem is learned; S_1 occurs when one or the other subproblem is learned; and S_2 occurs when both are learned. This model gave excellent predictions; only the predictions for the standard deviations of the total number of errors and the trial of the last error failed to describe the results obtained. Trabasso and Bower suggest that this latter failure might be due to interference from the first-learned subproblem while the second subproblem was being learned. Although this experiment shows that the original cue-selection model bears up well when it is extended to more complex situations, a study by Crawford, Hunt, and Peak (1967) on disjunctive problems indicates that the model as stated cannot be automatically applied to all concept-learning problems. Crawford et al. did not obtain stationarity—in fact, there was an increase in the probability of an error before the last error, a result contrary to the predictions of almost all present-day learning theories. In another experimental procedure, Mandler, Cowan, and Gold (1964) and Grier and Bornstein (1966) also failed to observe stationarity. In their experiments, they varied the relative frequency of stimuli so that one of the category responses occurred more than half the time. Subjects increased the frequency with which they made the higher-frequency category response, thus showing a kind of probability learning.

Direct search for hypotheses A basic assumption of the cue-selection model is that reinforcement affects hypotheses and not responses themselves; responses are determined by the current hypothesis that the subject holds.

Levine (1963) has extended his theoretical analysis of human discrimination learning to human concept learning. He modified the successive procedure by taking a four-dimensional binary-valued problem and, instead of presenting a single stimulus on each trial, he presented pairs of orthogonal stimuli. Such pairs have a different value for each dimension on the two stimuli. The innovation in his experimental design was the introduction of blank trials. On such trials, the subject was not informed whether or not his response was correct. By presenting four stimulus pairs ordered as in Table 20.4, he could analyze the subject's guessing behavior on blank trials, thus determining which hypothesis the subject was using. In Table 20.4, the left stimulus of the pair is specified by the values on each of its four dimensions—the same is true for the right stimulus. Each of the four hypotheses corresponds to selecting one of the dimensions and responding consistently to it. There

are two versions for each hypothesis, depending on the particular stimulus that the experimenter calls correct. In most of Levine's work, the subjects are sufficiently familiar with the problem so that it can be assumed that they will pair the correct response with the correct value.

Levine showed that subjects have what he calls "prediction hypotheses." These are hypotheses that change as a function of reinforcement. Subjects do not have response hypotheses independent of reinforcements. By instructions and simple experimental demonstrations, the subject can be "set" to use one of the four hypotheses listed in Table 20.4. The proportion of each hypothesis used can be determined by fairly simple arithmetic operations. From his experimental analyses, Levine concludes that (1) the hypothesis and not the response per se is the unit of behavior affected by reinforcements; (2) a hypothesis is not a response pattern but a mediational response that can reasonably be considered to exist even on nonoutcome trials; (3) human subjects, in contrast to animals, use prediction hypotheses depending on outcomes and not response hypotheses independent of outcomes.

Another set of experiments by Levine, Leitenberg, and Richter (1964) established the "blank trial law." Four experiments were run: a 2-trial discrimination experiment, a modified double-alternation experiment, a contingent discrimination experiment, and a probability-learning experiment. In each of these four experiments, four specific trials were set apart, and a contrast was made between (1) reinforcing the subject on each of these trials by telling him that he was right and (2) telling him nothing, that is, the blank-trials procedure. In none of the four experiments was there a difference in the pattern of responses over these four contrasted trials. From the results of these studies, Levine et al. conclude that telling the subject that he is correct serves to maintain the mediational response, but that giving the subject no information about whether he was correct or not also serves to maintain the same mediational response. The reinforcing effect of "right" is not to fix a response or make it more likely. The law then states that the effect of no information is the same as the effect of saying "right."

Two more experiments involving the use of blank trials provide some pertinent facts about concept learning. In 1966, Levine reported an experiment in which 16 trials were given with stimuli as presented in Table 20.4. On trials 1, 6, and 11, the subjects were given outcomes, but all other trials were blank. All eight possible patterns of outcomes over these three trials were given (that is, right-right-right; right-right-wrong; right-wrong-wrong, and so on). The patterns of responses on the blank trials were of primary interest. First, 92 percent of the hypotheses were of the four types listed in Table 20.4. Furthermore, if a hypothesis was confirmed (on trials 6 or 11), then it was retained with probability .95. If it was not confirmed on trials 1, 6, or 11, it was retained with probability .02. This finding contradicts the assumption of the cue-selection and hypothesis-selection models, which assume sampling with replacement. If the hypothesis were replaced, it would be resampled with probability .125. Further refined analyses are possible. On the first trial, if the experimenter says "wrong" the subject can eliminate four of the eight hypotheses. His probability of selecting from the remaining four should then be 1.0; it was found to be .87. Presumably, on the average, subjects nearly eliminate—but not completely—the four erroneous hypotheses. This analysis can be carried out over the three outcome trials. If, on each outcome trial, the experimenter said "wrong," the number of hypotheses would be reduced by one-half, so that theoretically the subject could be correct on trials 12, 13, 14, and 15. On the other hand, if subjects replaced erroneous hypotheses and did not learn from the feedback, they would remain at chance and still be selecting from the original eight hypotheses on trials 12 to 15. Levine found that subjects did eliminate hypotheses, but not by one-half, each time

they were told that they were wrong. Finally, an unexpected result was that, even on successive "right" feedback outcome trials, the subjects continued to learn about the correct hypothesis. Levine found that the probability of selecting the correct hypothesis on the last four blank trials after three "wrong" outcomes was less than after two "wrong" outcomes, which in turn was less than after only one "wrong" outcome. Levine suggests that the subject encodes the stimulus chosen on each outcome trial. When another outcome trial occurs, he encodes the intersection of the previously encoded stimulus and the correct stimulus on the current trial. That is, the subject uses a focusing strategy. In contrast, if an outcome trial is "wrong," the subject must forget the old dimensions and encode the new dimensions—hence the increased efficiency of "right" in this experiment. Levine's experiment, of course, differs from the usual procedure on which outcomes are produced on every trial; the four intervening trials may aid the subject in forming his hypotheses.

Levine, Miller, and Steinmeyer ran another experiment (1967) in which the blank-trial procedure was used to probe the hypotheses used by subjects. The procedure was similar to that of Levine (1966) except that trials were presented until learning occurred. Again, every fifth trial was an outcome trial and the four intervening trials were blank trials. The error stationarity curve, defined by outcome trials before the last error, was stationary, but it was above the expected chance level of .5. The hypotheses inferred from the blank trials were limited to the reasonable ones indicated in Table 20.4 except that, prior to the trial of the last error, the correct hypothesis did not occur. The hypothesis which is the complement to the correct one also did not occur, suggesting that subjects determine their responses by dimensions and not by values. Immediately after the trial of the last error, the four blank trials indicated that subjects had attained the correct hypothesis with a probability of only about .95. The low probability (.95 instead of 1.0) of the correct hypothesis after the trial of the last error is unexplained. Perhaps the most interesting result is the fact that, prior to solution, the subjects made more errors than we would expect by chance. The analysis by Levine et al. depends on the fact that the four blank trials are orthogonal, as is indicated in Table 20.4. These blank trials have two important features: (1) no attribute is paired with the correct attribute for more than two trials, and (2) for any two trials only one attribute is so paired. These restrictions, along with the assumptions that subjects tested only the hypotheses listed in Table 20.4, maintained their hypotheses when right, and switched when wrong, lead to two predictions. First, if the subject was maximally efficient in eliminating hypotheses, his correct performance would be about .33 by chance. Second, if the subject eliminated no hypotheses when wrong, his chance performance would be .415. Interestingly, the more efficient strategy leads to poorer presolution behavior. Levine et al. observed a presolution level of about .38, which is somewhere in between these two predictions.

There seems little doubt that subjects select cues or test hypotheses in the simpler concept-learning tasks where instructions are explicit and the dimensions clearly labeled. The cue-selection model is weakest in its assumption of no memory. A number of experiments reported here have shown that memory for previously tested hypotheses as well as memory for past stimuli and their assignments (at least on the immediately preceding trial) enter into the behavior of subjects when they are selecting a hypothesis (see Hunt, 1961; Trabasso and Bower, 1964b). Further studies must investigate more complex learning problems.

Concept-Learning Variables

The learning of concepts is a complex process. By restricting the class of stimuli and instructing subjects carefully, a reasonably reliable set of results can be obtained. As we

have seen, such results have been adequately described by the simple cue-selection model. However, as stimuli are made more complex, as rules are expanded, and as procedures are modified to conform more with concept learning in real-world situations, a number of new variables will have to be investigated and accounted for by modifications of the model. We discuss here some of the results obtained so far by various investigators using different stimuli, rules, and procedures.

Perceptual processes Heidbreder's basic idea (1947) was that different concepts could be ordered according to their perceptual bases. She concluded that objects were easiest to classify, followed by shapes, and that abstract or analytical concepts such as number were most difficult. In a series of experiments using the Wisconsin Card Sorting Test or Weigl-type card sorting test (Grant, Jones, & Tallantis, 1949; Grant, 1951; Grant & Curran, 1953), Grant and his coworkers found that in some cases number was the easiest of the three dimensions used (color, form, and number). In later experiments, when the number involved was not clearly laid out perceptually, number was about as difficult to classify as form but still easier than color. This change in the difficulty of classifying the concept "number" came about when the number was arranged in unsystematic configurations instead of symmetric patterns. Grant's results relate to the weight of the dimensions as discussed in the cue-selection model; from such results, we must conclude that weight is a function of configural arrangements.

Another study that manipulated the weight of cues was that of Trabasso (1963), who varied the saliency by what he called "emphasizers"— adding color to cues or making the values more discriminable, for example. In studies of concept learning, the values themselves on any dimension must be discriminable or else a discrimination problem will be mixed with the concept problem. If two stimuli differ in size, but are not easily discriminable because of successively presented stimuli, the subject may simply confuse the value observed. Certainly, this variable will determine the weight of the dimension. Unfortunately, there is at present no theory to determine the saliency of cues.

Problem type In their very complete discussion of concept learning, Bruner, Goodnow, and Austin (1956) note that subjects use a variety of strategies to solve concept problems. These strategies are related to the procedures used to present the stimuli and to the type of concept (conjunctive and disjunctive). One of the first universally observed facts in concept-learning literature was that subjects find conjunctive problems much easier than disjunctive problems. Related to this finding is the finding that subjects seem to prefer positive instances (objects that are exemplars) to negative instances (objects that are not exemplars) and utilize the information contained in positive instances more thoroughly.

We shall first discuss conjunctive rules, that is, rules in which the intersection of two values from each of two dimensions defines the concept. One presentation procedure is to lay all the stimuli in the universe before the subject and present him with one stimulus that is either positive or negative. The subject's task is to select stimuli that are exemplars and to state the rule when he thinks he knows what it is. This procedure resembles the experimental approach in that a hypothesis is stated and stimuli are chosen to test it. The *simultaneous scanning strategy* assumes that the subject considers all possible hypotheses that remain after the first stimulus has been presented and selects another stimulus that will reduce this set of hypotheses by the greatest amount. No subject can use this strategy efficiently because it requires a very large memory and a great deal of analysis to determine the implication of each selection. A strategy requiring little memory and giving the subject a direct test of his hypothesis, rather than the negative test provided by

the simultaneous scanning procedure, is the *successive scanning strategy*. Here, the subject chooses one hypothesis and selects a stimulus to test it. If the stimulus is positive, the hypothesis is retained, whereas if the stimulus is negative, another hypothesis is selected. Of course, the subject should also remember all the rejected hypotheses in order not to use them again.

In contrast to the scanning strategies are the focusing strategies. In *conservative focusing*, the subject selects a positive instance and systematically varies one dimension at a time. If the dimension is relevant, it is retained in the hypothesis; if irrelevant, it is dropped. The first positive instance contains all relevant dimensions and a number of irrelevant ones. The procedure is quite efficient, for no test is redundant with previously tested stimuli. The subject has to remember only a list of the values on each dimension, but he may test more than one dimension when he chooses the next stimulus; such a strategy is called *gambling focusing*. The problem with "gambling" is that, if the selected stimulus is negative, either the subject ignores it or he reverts to simultaneous scanning and analyzes which hypotheses were eliminated by the negative instance. Bruner et al. found that the learning rate was a direct function of whether subjects used successive scanning or conservative focusing. They also found that some subjects used a kind of successive scanning in which they tested more than one hypothesis at a time.

When the procedure is changed so that the experimenter determines the order in which the stimuli are presented, the subject must change his strategies because instances come his way without his being able to control their order. The subject must emphasize the hypotheses to be tested rather than the stimuli to be selected. These are called *reception strategies*. Bruner terms the strategy analogous to the focusing strategy under this procedure the *wholist strategy*. The subject uses the first positive instance to compile a list of values and then classifies stimuli according to the list held in his memory. Any stimulus with a different value from the value held in the list is classified as negative. For example, the first positive instance might be a large red circle on the left. The next stimulus might be a large red square on the left and would be classified by the subject as not being an example of the concept. If indeed it were not an example, the subject would not change his list. However, if it were an example, the subject would eliminate shape from his list because it has been found irrelevant. His list then consists of a large red object on the left. If the subject makes no errors in using the wholist strategy, a stimulus with all different values (for example, a small green object on the right) must be negative. Here, no information is gained. Eventually, all irrelevant dimensions are eliminated and the subject is left with the pair of values that defines the conjunctive concept.

Scanning strategies also may be used with the procedure under which the experimenter presents the stimuli. Again, the simultaneous scanning strategy is so taxing in terms of analysis and memory that no subject could use it. It requires, at each stimulus presentation, that the subject consider all hypotheses and eliminate all those that are disconfirmed by the examples presented so far. The successive scanning strategy, the strategy assumed in the cue-selection or hypothesis-selection model previously discussed, is reasonable but not especially efficient. Bruner et al. state that subjects use a more elaborate strategy—the *partist strategy*—in which more than one hypothesis is considered at a time. If, according to the subjects' current hypothesis or hypotheses, a stimulus is positive and should be, or if it is negative and should be, then no change is made in the hypotheses considered. However, when a subject incorrectly assigns a stimulus, he must form a new hypothesis consistent with the old and the new information. As with the selection strategies, the reception strategies vary in efficiency, and subjects using the different strategies accordingly vary in the number of trials

they take to solve problems. Further details of how and when subjects use these strategies can be found in Bruner et al. (1956).

With disjunctive concepts, the strategies thus far discussed present immediate problems. For example, consider the disjunctive concept of all red and/or square stimuli. The strategies discussed above would eliminate red when a green square occurred and would eliminate squares when a red circle occurred. The appropriate strategy is *negative focusing,* in which a negative instance is selected and dimensions are varied one at a time. The set of dimensions that remains defines what the concept is not—a conjunctive definition that is the complement of the correct disjunctive concept. Most subjects attempt common-element solutions, hypotheses that contain only the values that have always been correct. Two factors seem to make disjunctive concepts more difficult to learn than conjunctive concepts: One is that subjects tend to use strategies appropriate for conjunctive concepts but not for disjunctive. The second is that subjects tend to avoid negative formulations, even though negative formulations make disjunctive concepts relatively simple.

Hunt and Hovland (1960) presented subjects with sets of positive and negative stimuli for which one conjunctive, one relational, and one disjunctive concept were all compatible. Following this pretraining, the subjects were asked to select exemplars of the concept from a set of unlabeled stimuli. The subjects selected conjunctive and relational stimuli significantly more often than disjunctive stimuli, indicating that, given an ambiguous situation, subjects would conclude that a concept was conjunctive or relational more readily than they would conclude that it was disjunctive.

Wells (1963) found that subjects who had previously learned a disjunctive concept increased the proportion of disjunctive concepts selected when a given set of stimuli was compatible with either a conjunctive or disjunctive concept. In a second experiment, Wells found that an exclusive disjunctive concept (*A* or *B* but not both) was harder to learn than an inclusive disjunctive concept (*A* or *B* or both). This tends to support the explanation given by Bruner et al. that conjunctive concepts are easier to learn because subjects look for common positive values. The stimulus containing both values would appear crucial in this respect and could account for the difference observed in these two disjunctive concepts.

Conant and Trabasso (1964) set up an experiment in which the conjunctive and disjunctive problems were structurally, perceptually, and informationally equivalent. The 16 stimuli consisted of a triangle on the left and a circle on the right. Each shape varied in size (large or small) and color (red or green). The subjects were clearly instructed about the two types of concepts possible and were first given a card identified as positive or negative. The subjects then selected stimuli until they had decided on the correct concept. Conant and Trabasso found that the conjunctive concept was easier to learn than the disjunctive; the subjects tended to select positive instances sooner than negative instances. However, their subjects eventually did show positive focusing strategies for conjunctive problems and negative focusing strategies for disjunctive problems. The responses on the disjunctive concepts were more redundant, accounting for most of the difference between the learning rates. Conant and Trabasso noted the problem of verbalizing a disjunctive concept. They analyzed the trial of the first concept that was verbalized and found no difference in trials until the first stated hypothesis, but the conjunctive concepts were right 75 percent of the time while the disjunctive concepts were right only 56 percent of the time.

Crawford, Hunt, and Peak (1967) unsuccessfully attempted to apply the cue-selection model to disjunctive concepts. Stationarity was not obtained because, interestingly enough, the proportion of errors made increased over trials. Thus, disjunctive concepts are not learned in an all-or-none fashion. The

authors suggest that the Trabasso and Bower (1964a) four-category model (developed earlier for the two independent affirmative concepts) might be more appropriate.

In evaluating the use subjects make of positive and negative instances in concept learning (CL) it is necessary to determine the amount of information that each instance provides. An early study by Smoke (1933) concluded that subjects made no use of negative instances, but Smoke failed to take into account the amount of information that the negative instances provided. If, for example, the concept is a simple affirmative one and there are more than two values on a dimension, then a negative stimulus yields less information than a positive one. Hovland and Weiss (1953) ran an experiment with three dimensions (color, form, and number) with two values each in which the solution was a simple conjunctive one. Such a problem requires a minimum of two positive instances and five negative instances. For example, if "red-square" is the concept, and the first and second positive stimuli are 1-red-square and 2-red-squares, the subject can select the correct concept. However, the five negative examples, 2-red-circles, 1-black-square, 1-red-circle, 2-black-circles, and 2-black-squares are required to convey the concept by negative instances. The subject was instructed to look for a conjunctive concept and was shown each of these instances successively for 5 sec each and afterwards was asked to state the concept. All stated the correct concept when positive instances were given but only 16 percent stated the correct concept when all negative instances were given. Because it took 5 negative instances to provide information for solution but only 2 positive instances, a memory difference is obviously a possible factor here even though the information transmitted has been controlled. In a second experiment, Hovland and Weiss eliminated the memory factor by presenting all instances at once. Again, significant differences occurred in favor of the positive instances. In a third experiment, they equated the number of instances as well as the information content of the simultaneously presented stimuli. Once again, the results clearly indicated the superiority of positive instances, but also clearly showed that subjects do learn from all negative instances.

A distinction which must be made in all studies concerning the difficulty of problem types is whether the observed differences reflect past training and/or a bias in the way most concepts are defined in our culture, or whether an innate processing difficulty is involved. Freibergs and Tulving (1961) raised this question with respect to the Hovland and Weiss results in which subjects were not given practice. Freibergs and Tulving presented one group of subjects with a successive series of all positive stimuli and another group with a successive series of all negative instances. There was a substantial difference between the responses made by the two groups during the early problems; negative instances were not used at all efficiently. However, by the end of 20 problems, there was almost no difference and subjects showed great improvement in the speed with which they could name the concept after the presentation of the 4 positive or negative instances.

There are still gaps in our knowledge about the use of positive and negative instances. Freibergs and Tulving's results may not hold up for problems more complex than conjunctive ones. Further studies with concepts other than conjunctive and affirmative are needed. The best explanation for the results obtained thus far seems to be that subjects have a learned bias to use positive focusing or wholist strategy and these strategies utilize positive instances only. This bias can be modified when it is not useful, but such modification takes practice or a thorough knowledge of the nature of the problem. Studies by Wason (1959, 1960, 1961) indicate that this bias for positive instances extends to forms of problem-solving tasks other than those specifically discussed here.

We can now turn to other concepts, such

as those called the *biconditional* and the *conditional concepts.* The first study to investigate a broad class of concepts was that of Neisser and Weene (1962). They noted that the concepts in Table 20.3 could be ordered on three levels. The concepts on the second level are defined in terms of those on the first, and those on the third in terms of those on the second. This ordering depends on assuming that negation, conjunction, and disjunction are the basic operations as opposed to other logical operations. All second-level concepts are defined from a conjunctive or disjunctive combination of affirmative or negative instances, whereas all third-level concepts require a combination of second-level concepts. For example, exclusive disjunction, $A \overline{\text{or}} B$, can be (A or B) and ($\overline{A \,\&\, B}$). Their stimuli were strings of four consonants (for example, *JQVZ, JJQZ, QJZZ,* . . .) where order was unimportant. The concepts were defined on the basis of the presence or absence of a pair of letters. Neisser and Weene concluded that problems were ordered in terms of difficulty according to the three levels, and argued that the ordering has some relationship to the definitions of the levels, that is, the basic operators required.

Haygood and Bourne (1965) provided a more complete analysis of concept learning. They first noted that the usual concept-learning (CL) problem is ambiguous in two respects: First, the subject does not know the dimensions used in defining the concept, and, second, the subject often is not clearly told what the rule is (that is, he is not always told that it is a conjunctive or disjunctive concept, for example). However, even when told the rule, the subject's past learning may have been appropriate for conjunctive rules but not for disjunctive rules. Haygood and Bourne therefore suggest that three types of problems be considered. One is called *attribute identification* (AI), under which the subject is clearly informed and practiced in using the appropriate rule but is not told what the necessary dimensions for solution are. The dimensions are still assumed to be readily namable and codable. The second type of problem is *rule learning* (RL). Here the dimensions and the rule are given to the subject, but presumably before he knows how to use them. Through practice problems, the subject learns to use the rule appropriately. The third type of problem is that of *rule identification* (RI). Here the rules have been learned according to the rule-learning paradigm, the dimensions are given, but the particular rule in force is not known. The subject must determine whether a conjunctive, disjunctive, or biconditional rule defines the concept, for example.

This analysis by Haygood and Bourne clarifies the task and what is involved in it. By presenting subjects who know the rules with rule-identification problems, the intrinsic difficulty of utilizing rules can be judged. By presenting rule-learning problems, the difficulty of learning the rules can be evaluated. Also, in the AI problems, the selection process assumed for earlier studies becomes less likely to be mixed with rule learning or rule identification. In a factorial experiment with four rules and three procedures (AI, RL, and CL), Haygood and Bourne found that CL in which both the rule and the relevant dimension were unknown was more difficult than AI, which in turn was more difficult than RL. There was steady improvement over the five problems (all with the same rule) that each subject received. Listed in order of increasing difficulty, the rules used were conjunction, joint denial, inclusive disjunction, and conditional. The difficulty of the conditional is due to the high number of positive focus instances (AB, $\bar{A}B$, and $\overline{AB}$) and to the fact that both AB and $\overline{AB}$ are positive instances. Haygood and Bourne suggested that another reason the subjects had difficulty with the conditional rule is its asymmetry; that is, $\bar{A}B$ is positive but $A\bar{B}$ is negative. This asymmetry means that the subject must maintain the correct order of the rule; "red and not square" is an example of the concept but "not red and square" is not. All rules except the conditional were learned well

enough so that by the fifth problem subjects were performing perfectly. Although the AI learning was poorer in terms of number of errors than RL, the comparison is not justified without further analysis. In AI problems, some errors are necessary, while in RL the subject can learn without errors. The most efficient learning possible for AI problems would give 4.7, 10.8, 9.7, and 8.0 as the minimum expected trial of the last error for the conjunctive, inclusive disjunctive, joint denial, and conditional problems, respectively. Haygood and Bourne observed 7.4, 16.0, 16.6, and 34.0, respectively, indicating that subjects were not using a simultaneous scanning strategy since performance would have been optimal if they had been.

In their second experiment, Haygood and Bourne investigated rule identification (RI) after prior RL training on four different rules from Levels II and III (Table 20.3). The subjects received three training problems—a disjunctive, a conditional, and a biconditional. Following these training problems, subjects were presented with two RI problems. They did not solve the problems with maximum efficiency, but they did show transfer from RL problems, indicating transfer across problem types. In RI, the biconditional and conditional rules were more difficult than the conjunctive and disjunctive. An analysis of the learning of each combination of patterns (AB, $\overline{A}B$, $A\overline{B}$, and $\overline{AB}$) showed that, before the last error was made on each combination, the subjects performed at about chance for that combination, that is, .56 in RL and .53 in RI. The difficulty of the pattern combinations helped in the analysis of why conditional and biconditional problems are more difficult. In the biconditional problem, for example, where AB and $\overline{AB}$ are both positive, the strategy of looking for common elements would fail completely. Similarly, under the conditional rule, the combination $\overline{A}B$ and $A\overline{B}$ is particularly difficult. According to Haygood and Bourne, subjects did not attain perfect performance in RI because they did not learn well enough the mapping of responses to the combination of values. Haygood and Bourne conclude that rule learning (RL) is a 2-stage process: The first stage is learning to recode the stimuli in the four combinations AB, $\overline{A}B$, $A\overline{B}$, and $\overline{AB}$, and the second stage is learning the response assignment that goes with each combination for each rule.

In a follow-up report of research on RL and AI, Bourne (1967) discussed various attempts to show that subjects do in fact recode the stimuli into four relevant classes. He reported that with extended problems and "sample patterns illustrating the proper response assignment of each of the four stimulus classes," subjects could learn conjunctive, disjunctive, conditional, and biconditional problems without errors, although subjects took longer to reach perfect performance on conditional and biconditional problems. The difference in the difficulty the subjects experienced with different problem types was accounted for by the response assignments: "Particularly noteworthy are class *FF* for the conditional and biconditional problems and classes *TF* and *FT* for the conditional. . . . The asymmetry of the conditional rule produces a unique difficulty in handling *TF* and *FT* instances." (*FF*, *TF*, and *FT* instances are our $\overline{AB}$, $A\overline{B}$, and $\overline{A}B$ classes, respectively.) When subjects were given a number of different types of problems they performed better. The reason seemed to be that, when mixed problem types were presented, the nature of the conditional and biconditional problems was highlighted. It must be emphasized that, in all the experiments reported by Bourne, the first presentations of problem types varied in the ease with which they could be learned. Only by providing practice and clear separation of rule learning from attribute identification was Bourne able to obtain perfect performance on all problems. He emphasized that the change in the subjects' performance is a change in the way they encode the set of stimuli; that is, they eventually reduce the problem to one of learning four paired-associate assignments.

In an extensive study of simulation of concept identification and artificial intelligence,

Hunt, Marin, and Stone (1966) ran three experiments involving the following problem types: (1) conjunction, (2) inclusive disjunction, (3) conditional, (4) exclusive disjunction, and (5) biconditional. (These problem types were run to be compared with a variety of concept-learning systems (CLS) which will be discussed later under information-processing models.) Their experiments used a successive reception presentation procedure, but, unlike the usual procedure as used by Bourne, for example, the stimuli were left in view of the subjects (experiment X) or were presented in sets (experiments XI and XII). The results of the first experiment are consistent with previous results: According to ease of learning, the groups above were ordered 1, 3, 2, 4, and 5. Hunt et al. were concerned that subjects might not have attended to all the stimuli because, at times, up to 40 stimuli were present for the subject to look at. Therefore, in experiment XI, a set of 16 stimuli, 8 positive and 8 negative, were presented, and the time it took for the subject to announce the solution was recorded. The order of learning based on the time it took the subject to reach a solution with this procedure was only slightly different: 1, 2, 3, 4, and 5. In experiment XII, a slightly different procedure was used, but again with similar results. Hunt et al. conclude, along with Neisser and Weene (1962), that these differences in the difficulty of problem type reflect differences in subjects' hierarchical organization of conceptual processes and not a difference in the amount of information being conveyed or needed to solve the various problems. To show that amount of information was not the relevant variable, Neisser and Weene (1962) used a maximally efficient artificial concept-learning system, under which a simple conjunction took longer to learn than the more complex problems. In other words, there was actually more information provided to real subjects in the complex problems but they were still solved more slowly. Hunt et al. were comparing their subjects' results to the prediction of concept-learning theory based on an information-processing model. One model they considered had no memory limitations and thus the experiments they ran were such as to require no memory on the part of the subjects—all stimuli were continuously present for analysis by the subjects. Their CLS model is based on the following set of information-processing rules:

(1) A search is made of the available set of stimuli for some characteristic (value or dimension) or set of characteristics associated with only the positive instances of the concept.

(2) If no such characteristic(s) is found in (1), then a set of characteristics common to all negative stimuli is the object of the search.

(3) Given that both steps (1) and (2) fail, the CLS determines which value occurs most frequently in the positive instances only. The set of stimuli are divided into two subsets on the basis of this value (present or not present) and steps (1) and (2) are repeated separately for the two subsets. After (3), when the CLS tries to find common values for subsets, the process may again fail, and step (3) may be repeated on a subset. The process is thus recursive in its application.

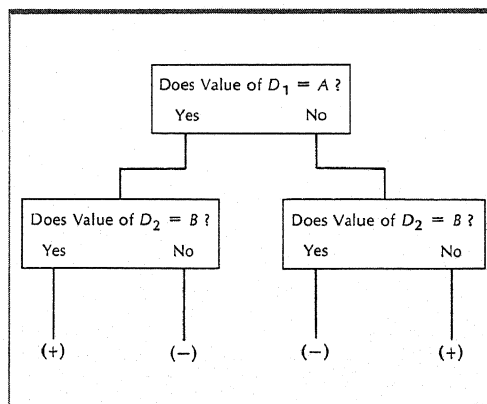
The results of the CLS can be represented in tree notation. For example, an efficient solution to a biconditional problem is illus-


Figure 20.11. Decision process necessary to solve a biconditional problem with focal values A for dimension D_1 and B for dimension D_2. (See Table 20.3 for details; adapted from Hunt et al., 1966).
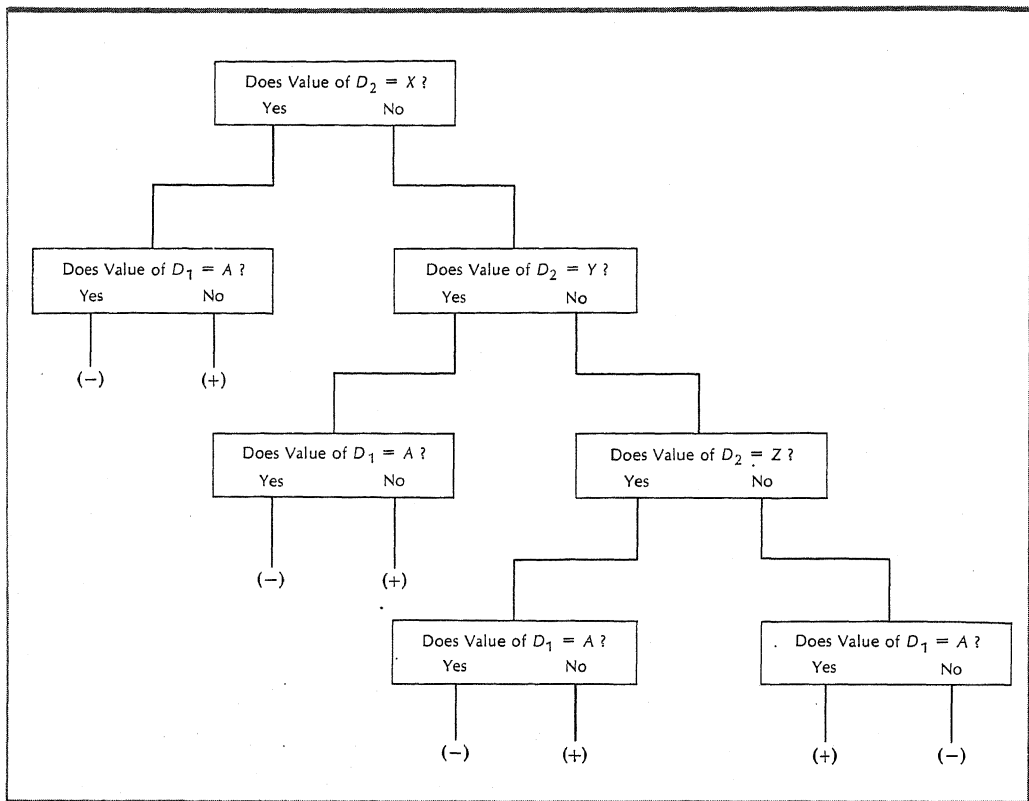

Figure 20.12. Decision tree formed by CLS-1 for a biconditional concept after presentation of 31 items. Items remain available until a solution is reached. Focal values are $D_1 = A$ and $D_2 = B$. Other values of D_2 are X, Y, and Z.

trated in Figure 20.11. Note that the CLS system would not necessarily develop the tree indicated in Figure 20.11, for the items would be presented in random order and a more elaborate tree might result. In Figure 20.12, an example of the results obtained by Hunt et al. is presented. The important point to note here is that the difficulty of the problem is supposedly related to the kind of tree that must be developed in order to solve the problem. Hunt et al. show by their simulation work that, in a general way, the rank order of the problem difficulty is reproduced by the CLS model described above. The model just presented has no memory limitations, but in a second version, Hunt et al. limited memory so that only a small number of stimuli were worked on at one time. There is little difference in the performance of the two models. We shall say more about simulation models later; our main purpose here is to present the results for various concepts where memory is not a limitation and to show that the difficulty of the various problems lies in the nature of the information that must be processed.

A paper of great theoretical importance (Shepard, Hovland, & Jenkins, 1961) provides some further information about the difficulty of learning various concepts. The stimuli for the experiments consisted of three binary dimensions. A number of different sets of stimuli were used. For example, in one set of eight stimuli the dimensions consisted of pictures: (1) a candle or light bulb, (2) a screw or nut, and (3) a violin or trumpet. Other sets were similarly made up. Another type of

TABLE 20.5 THE SIX CONCEPT TYPES USED BY SHEPARD, HOVLAND, AND JENKINS

Number of each type				6	6	24	8	24	2

*Type I is affirmative or equivalently negative; Type II is biconditional or equivalently exclusive disjunctive (see Table 20.3).
†Types III through VI depend on all 3 dimensions.

Adapted from Shepard, Hovland, & Jenkins, 1961.

stimulus was called "compact" because all values were represented in a single stimulus, for example, a small, black circle or a large, white triangle. The compact stimuli were contrasted with "distributed" stimuli, which consisted of three figures (triangle, circle, and square) each of which was used to represent one of the three dimensions. In one distributed representation each figure could be either small or large, thus providing the eight stimuli. In another representation, the triangle could be large or small, the circle black or white, and the square grey or white.

In contrast to most of the experiments discussed so far, all three dimensions were required to define most of the concepts used by Shepard et al. In all cases, the set of eight stimuli was partitioned into two equal subsets of four each. There were 70 such partitions, but only six different ones. These are presented in Table 20.5. The Type I concept consists of the simple affirmative and negative concepts, and the Type II is the biconditional and exclusive-disjunctive concepts as illustrated in Table 20.3. These pairs are combined here because only binary-valued dimensions are involved, and, of course, the affirmative and negative pair depends on only one dimension while the biconditional and exclusive-disjunctive pair depends on only two dimensions. Types III through VI depend on all three dimensions. The number under each concept type indicates the number of stimulus configurations of the 70 associated with each of the six basic types.

In the first experiment, subjects learned all six concept types in different orders. Five problems of each type were learned before another type was presented. The total time to learn each response assignment, the trial of the last error, the total number of errors, and the errors in the first 32 trials were all measured and were highly correlated with each other. The ranking of difficulty of the problems was I < II < (III = IV = V) < VI. With extended training, Type VI moved in between Type II and (III = IV = V); the others remained as ranked above. In an attempt to determine why these classification types were ordered in the way they were, the authors classified the verbal statements of the subjects concerning the rules used to solve the problems. The classification was made in terms of the complexity of the stated rule. The number of errors and mean rating of complexity were as follows for the 6 ordered types: (errors, rated complexity) = (8.3, 1.6), (13.2, 1.7), (32.0, 2.9), (16.7, 1.8), (23.6, 3.2), and (28.0, 2.3). These have a correlation of $r = .80$, which is significant. Thus, the difficulty in stating a rule was highly correlated with the errors produced.

In their second experiment, Shepard et al. tested rule formulation and memoriza-

tion by presenting subjects with the eight stimuli appropriately divided. For the rule-formulation task, they asked subjects to state the rule that defined the partition; for the memorization task, they asked subjects to re-sort the stimuli. Again, the rank order of ability to state rules and/or memorize the classification was I < II < (III = IV = V) < VI. In experiment II (and experiment III, which was a replication of experiment II), the compact and distributed stimulus sets were used. These different sets did not substantially change the results. The classification types II through VI became more difficult with the distributed stimuli. Type I was unaffected. Only some main points of their extensive analysis can be mentioned now. The first is that subjects abstract relevant dimensions from stimuli in any learning problem. The second point that the authors make is that subjects use Type I classifications to formulate rules for building up higher-order classifications. Shepard et al. feel that the rank order observed can best be understood with this kind of explanation, essentially the explanation that Hunt et al. have more recently offered.

Memory Factors

The role of memory was mentioned briefly during the discussion of the all-or-none hypothesis or cue-selection model. Trabasso and Bower (1966) questioned the assumption that a hypothesis was selected on error trials with replacement; they introduced a modified version of the model which assumed that selection was limited to agree with the information received from the error trial and from the preceding trial. As was mentioned earlier, the Dodd and Bourne (1967) experiment raised questions about that interpretation.

The rather limited literature on the role of memory in concept learning indicates that memory is not independent of the strategy used by the subject. Concerning the selection-strategy procedure where the subject himself selects the stimuli to test, Bruner et al. (1956) discussed two main strategies that subjects can use: successive scanning in which a single hypothesis is tested and conservative focusing (or positive focusing) in which a positive stimulus is used as a focus and successive stimuli are chosen to eliminate one attribute value at each choice point. The two strategies related to successive scanning and conservative focusing—simultaneous scanning and focus gambling—are not of importance here. The simultaneous-scanning strategy in which each stimulus is chosen to eliminate the maximum number of hypotheses requires an extremely large memory as well as many calculations on the part of the subject; it is never used perfectly by subjects when the stimuli are complex. Similarly, the focus-gambling strategy is used infrequently, not so much because it requires such a large memory as because it leads to errors and backtracking.

What are the memory requirements for the successive-scanning and conservative-focusing strategies? The successive-scanning strategy, the basic assumption of the cue-selection model, is analogous to the wholist strategy in reception procedure. No memory is required at first, but, as stimuli are chosen and hypotheses are rejected, the amount of information that must be remembered increases rapidly if optimum performance is to occur. Of course, as is the case with the cue-selection model, a solution can eventually be obtained without using any memory, but performance will not be very efficient. The conservative-focusing strategy requires the subject to remember all values of all attributes on the focus card (the first positive stimulus selected). As each dimension is tested and found irrelevant, that value can be dropped from memory. The rule for the choice of the next test stimulus is simple: Pick a stimulus which differs from the focus card in only one dimension. Thus, although early trials require a fairly large memory, memory requirements decrease over trials.

Bruner et al. ran a study to see if the performance of subjects using successive scanning and conservative focusing was

affected when the memory requirements in the task were increased. Twelve subjects were given three conjunctive problems consecutively. The first two problems had all stimuli ordered according to dimensions and values and all stimuli were clearly in view of the subjects. Five subjects solved these problems by successive scanning and seven by conservative focusing. The third problem was then presented, but the subjects were not allowed to see the stimuli. Because they had just worked with the stimuli, the nature of the problem was clear to them, but in the third problem all their tests had to be remembered. Subjects who continued to use conservative focusing performed just as well as before; two did not and showed a performance decrement. In contrast, the subjects using successive scanning required significantly more choices to solve the problem and their performance was less regular. If these results are generalized to the reception procedure used in all concept-learning studies tested by the cue-selection model, we see that because the stimuli are not in view the task involves the subjects' remembering all stimuli presented. Subjects who used the conservative-focusing strategy could still perform accurately and make use of their memory of previously presented stimuli. If there were a significant number of these focusers in problems used to test the cue-selection model, they could be detected only by the distribution of the trial of the last error, since their presolution behavior would remain at chance and the total number of errors statistic $E(T)$ would still be expected to be $gE(L)$. (See the section on Theoretical Analysis.) We do not know whether the statistical tests based on the distribution of the trial of the last error are sensitive enough to detect a small proportion of focusers in a sample of subjects. Procedures such as the one in which the relevant dimension is successively reversed on every other error (see p. 956) would render any attempt to use conservative focusing fruitless because the dimension switched to after an error might have been eliminated on an earlier error trial. The results of the SDS (successive dimensional shift) procedure suggest that, in experiments run to test the cue-selection model, few subjects consistently use a focusing strategy.

It seems intuitive that, in the successive-reception procedure, one difficulty for the subject is remembering past instances. Cahill and Hovland (1960) directly tested this supposition by comparing the performance of two groups of subjects. The successive group received stimuli one at a time with each stimulus being removed after the subject's response. The simultaneous group received the stimuli one at a time but stimuli remained in sight after being presented. The latter group performed much better than the former. Perhaps even more interesting was the fact that the hypotheses selected were consistent with the stimulus (or stimuli for the simultaneous group) within the subject's view. Most of the errors for the successive group were made when the subject selected a hypothesis inconsistent with a previously presented stimulus. Subjects who made more memory errors performed more poorly. Hunt (1961) took a slightly more refined look at the role of memory for previous stimulus instances. He presented subjects with three sets of stimuli. First, the key set was presented. It contained a varying number of stimuli before and after a critical stimulus. Then the second set was presented, which, along with the information from the key set, eliminated all but two hypotheses. The critical stimulus was relevant to a choice between these two hypotheses. The third set tested the hypothesis held by the subject. By this design, the ability of subjects to remember information from previous stimuli in the key set could be measured. The number of instances preceding the critical stimulus in the key set was not influential in determining the proportion of correct responses in the third set, but the number of instances following the critical stimulus was. These results are comparable to those of Cahill and Hovland but differ in that the latter noticed a primacy effect, whereas Hunt did

not; that is, Cahill and Hovland noticed a change in the effect of recent items as a function of the number of preceding items.

A third study on memory for previous instances was carried out by Bourne, Goldstein, and Link (1964). They extended the dichotomy of successive versus simultaneous presentation to a continuum by varying from zero to 10 the number of stimuli which remained in the subject's view. They found that a group with 10 stimuli in view showed poorer performance than a group with five stimuli in view! An explanation for the lack of continued improvement when more stimuli were exposed was offered by another experiment in which the subject was given no limit on the time to respond. The previous experiment had required the subject to respond within 15 sec; apparently, this limit pressed the subject so that he could not use the information from more than five stimuli, and the time limit actually produced a slight deterioration with more than five stimuli. Bourne et al. observed some other aspects of the role of memory with simultaneous presentation. Simultaneous presentation is more effective with complex stimuli than with simple stimuli. This seems to be due in part to the fact that simple problems are solved in a few trials and simultaneous presentation does not have a chance to become effective. Bourne et al. observed, in agreement with Cahill and Hovland, that simultaneous presentation reduced memory errors but not perceptual or logical errors.

The studies just discussed had easier memory requirements than the typical successive presentation procedure, that is, subjects had more stimuli in view. Restle and Emmerich (1966) introduced a procedure that increased the memory load over that of the typical successive-presentation procedure. Instead of learning one concept problem at a time, subjects had to learn two, three, or six at a time. This was done by presenting stimulus 1 of problem 1, then stimulus 1 of problem 2, then stimulus 2 of problem 1, then stimulus 2 of problem 2, and so on. Thus, for problem 1, there was an increased time between presentations of the stimuli and, probably more important, this time was occupied by the subject's attending to the stimulus of the next problem. Studies in short-term memory indicate that filled intervals produce a great deal of forgetting (Peterson & Peterson, 1959). Restle and Emmerich note that, according to the cue-selection model, as long as the memory for the single hypothesis being tested for each problem is not disrupted, the multiple-problem task should be no more difficult than the single-problem task. On the other hand, if the subject is remembering previous stimuli and selecting hypotheses on the basis of these stimuli, then reducing memory for previous stimuli by introducing multiple problems should make the multiple-problem task more difficult. Restle and Emmerich found that 1- and 2-problem tasks were not significantly different in difficulty, nor were 3- and 6-problem tasks, but the latter pairs were significantly more difficult than the former pairs. Apparently subjects begin to lose information at the point when three problems are being presented at a time. In their second experiment, Restle and Emmerich found that leaving the stimulus on for a longer period of time after feedback was given was beneficial for the 1-at-a-time problem but not for the 6-at-a-time problem. These results do not agree with those of a series of studies by Bourne and his coworkers (to be discussed later). In Restle and Emmerich's third experiment, the same stimulus was presented twice, separated only by the other problems in the multiple-problem condition. If a subject following the predictions of a cue-selection model does not remember the previous stimulus, then, (1) if he was correct on the previous stimulus, he will keep the same hypothesis and will be correct, but, (2) if he was wrong on the previous stimulus, he will select a new hypothesis and will be right or wrong at a chance level, provided that he does not select the correct hypothesis (that is, provided that there is a later error). However, if the subject remembers both the stimulus and the feed-

back, he will not make an error in either case (1) or case (2) above. Restle and Emmerich presented the repeated stimulus on an early trial (trial 3 or 4) and on a late trial (trial 24 or 25). When six concurrent problems were being learned, there was a significant difference, for the early-trial test, in the number of errors following correct responses and the number of errors following incorrect responses. Problems presented one at a time produced no such difference; the subjects showed excellent memory for the previous stimulus. The group that was given six concurrent problems did not do as well but still showed some ability to remember stimuli. On the later-trial test, the group given one problem at a time had all learned by trial 24, but the group given six problems at a time performed at chance.

Taking into consideration early theoretical ideas that concept learning is a variety of discrimination learning, Bourne (1957) wished to see the effects of delaying the reward in concept learning. He combined task difficulty, defined by the number of irrelevant dimensions (1, 3, or 5), with delay of reward (.0, .5, 1.0, 2.0, 4.0, and 8.0 sec between the subject's response and the reinforcing feedback). Both variables were significant in their effect. Learning became slower with greater delay of reward. The delay condition was handled theoretically by a trace model by Bourne and Restle (1959). An important aspect of this task was that the interval between trials was kept constant. Thus, as the reinforcing feedback was delayed, the time between the feedback and the presentation of the next stimulus was decreased.

Bourne and Bunderson (1963) then examined the effects of (1) delays of 0, 4, and 8 sec between the subject's response and the information feedback, and (2) delays of 1, 5, and 9 sec between the information feedback and the next stimulus (that is, with changing intervals between trials). They found no significant effect due to delays of type (1) but highly significant effects due to delays of type (2). The apparently contradictory results of the earlier Bourne study (1957) could easily be explained by the confounding of type (1) and type (2) delays in that study. The Bourne and Bunderson study raises serious questions about Bourne and Restle's theoretical analysis (1959) of the earlier Bourne study (1957), adds one more reason to reject the adaptation-of-cues model which Bourne and Restle introduced, and provides some further support to the cue-selection model. In a later study by Bourne, Guy, Dodd, and Justesen (1965), the intertrial interval was extended to 1, 15, and 29 sec. The stimulus was either present or not present throughout the interval, and the information feedback indicating the classification of the stimulus did or did not remain in the subject's view throughout the interval. The length of the interval and the presence of the stimulus throughout the interval were significant factors, but the continuous presence of the feedback signal was not. If the stimulus was absent, subjects with the 29-sec interval did more poorly than those for whom the stimulus was present, although with a 15-sec interval there was no difference due to this factor. The superior performance of the group with the 29-sec interval when the stimulus remained in view suggests that the subjects used this time to search the stimulus attributes and select another hypothesis. The poorer performance of the group working at the same 29-sec interval but without the stimulus left in view may reflect some forgetting of aspects of the stimulus or simple loss of attention and motivation. If the subjects did attend to other things during this time, the 29 sec is certainly a long enough period to produce large memory decrements. One interpretation of these results is that the subjects need the time after feedback to search the stimulus and choose another hypothesis to test.

All of the experiments discussed thus far have introduced variables that presumably change the memory for past stimuli in concept learning. Trabasso and Bower (1964b) made a direct test of how well subjects remember past stimuli. Subjects were presented with six stimuli in an affirmative problem with

four binary-valued dimensions. The subjects were told not only to solve the problem but to remember the stimuli. After the six stimuli had been presented, the subjects were asked to write their solution and then were tested for their memory of the six stimuli presented. On the test, the subjects were asked to describe the stimulus presented on trial x, where $x = 1 - 6$ in some random order different from the presentation order. The subjects circled one of two values for each dimension on prearranged data sheets. Trabasso and Bower found a small serial-position effect (stimuli presented on early or late trials were remembered slightly better than those presented on intermediate trials), whereas the order of recall did not produce an effect. The amount of recall above chance was less than one dimension per stimulus. Solved and unsolved problems were different, with the former showing better performance, particularly on the relevant dimension, and the latter showing better performance on the dimension stated in the hypothesis. All in all, there was little evidence for any substantial memory for the stimuli on past trials.

Although these findings may seem inconsistent with previously reported results, it must be remembered that the previous experiments mostly varied the demands made on memory, either by leaving the stimuli in the subject's view or by modifying the time the subject was allowed to look at a given stimulus. Performance of subjects in the Restle and Emmerich (1966) study in which the time between stimuli was increased would seem to imply that learning is a function of memory for past stimuli. However, a different explanation is possible. If concurrent problems are presented to a subject, not only may his memory for past stimuli be impaired (if indeed there is much memory for past stimuli), but his memory for the hypotheses tested on each problem may be impaired. There is here an important point about memory in concept learning, namely, that there are two kinds of memory. One is memory for stimuli and the other is memory for hypotheses tested and eliminated. Two experiments concern this very point. Erickson, Zajkowski, and Ehmann (1966) ran a successive-presentation concept-learning problem which was extremely well described by the all-or-none cue-selection model. They analyzed the latency of the subjects' responses, finding that latencies were longer on trials following an error than on trials following a correct response, but that latencies on the correct and error trials themselves did not differ. Erickson et al. used the Bower and Trabasso procedure (1963) of reversing the response assignments after every second error and substantiated their own expectation that latencies following uninformed errors would be equal to latencies following correct responses. Two of their predictions were not confirmed: One was that latencies after the last error would be constant and equal to latencies following correct responses; instead, they declined in a negatively accelerated function. The second prediction was that latencies before the last error would be constant; instead, latencies declined significantly. Erickson et al. explained the failure of the latter prediction by assuming that the pool of hypotheses from which the subject was sampling after an error was decreasing in size. They explained the difference in latencies following correct and error trials as being due to the time it took to sample another hypothesis—presumably no sampling occurred after a correct trial. Note that they assume that the sampling occurs on the trial following an error. This would probably not be true if the stimulus were left in view for a long time after the feedback (see Bourne et al., 1965). However, Erickson et al. presented the information feedback 2 sec after the response and only for 1 sec. Under such conditions, it is reasonable to assume that sampling occurs on the next trial.

The second experiment (Erickson & Zajkowski, 1967) was a follow-up to the previous one and consisted of simultaneous problems as in the Restle and Emmerich study. Erickson et al. introduced a reversal or a dimensional shift on every second error for

two of the problems; the third problem was a straight concept-learning routine. Thus they combined the Restle and Emmerich and the Trabasso and Bower (1964a) SDS procedures with good replication of both experiments. There was a large increase in the latency of response for these problems over that of their earlier study, but, more importantly, the latency for trials following an error did not decrease across trials. Their earlier explanation for the decrease in function across trials for these latencies was that the pool of hypotheses decreased. A consistent interpretation would hold that the pool was not diminishing in size in the multiple-problem concept-learning procedure. Thus, by introducing multiple problems, Restle and Emmerich may not be affecting memory for past stimuli, but rather they may be affecting memory for eliminated hypotheses. (A further discussion of this idea is presented in the section on information-processing models.)

In an early paper on the role of memory in concept learning (1952), Underwood discussed two ideas: *instance contiguity* and *spaced practice*. By instance contiguity he meant the degree to which instances associated with other concepts were interspersed among instances of the concept being learned. The standard successive concept-learning procedure has perfect instance contiguity whereas the Restle and Emmerich procedure introduces a great deal of irrelevant material between instances of the same concept. The spaced-trial problem is really the problem dealt with by Bourne (1957), and Bourne and Bunderson (1963). Dominowski (1965) has given a very good review of studies related to Underwood's hypothesis.

Information-Processing Theories

Definition and general discussion Psychological theory, like all theory, often proceeds by analogy. Descartes described man as being mechanically driven by fluids in tubes—a picture in line with the automata of his day. The associationists considered models of the association of ideas which followed the chemistry of their day. More recently, behaviorists developed models along the line of electrical switchboards. Today, we have the computer with which to form an analogy, and there is no denying the strong influence of computer technology on models of learning and thinking. Let us consider the analogy somewhat more closely. A computer consists of a number of special input and output devices. These can be considered as analogous to sensory systems or motor systems. The computer has a number of storage systems (core memory, disks, tapes, and so on) that can be considered analogous to memory systems. We do not yet know whether one or many types of memory should be posited for humans, but the distinction between a short-term memory system and a long-term memory system has natural parallels in the accumulator and the permanent core storage of computers. (This idea of short-term memory has received a great deal of emphasis in recent theoretical work, and will be discussed in more detail later; see page 997.) Another point about both human and computer memory systems worth mentioning is that the input signals stored are encoded versions of the original input. Computers do not store holes in punched cards or electrical impulses from switch closures. We do not store sound waves or light energy but patterns of nerve responses. Finally, at the level of physical hardware, the computer is a serial processor. This means that it considers one piece of encoded information at a time. The human system probably does not process input information serially, especially sensory input. However, with higher mental processes, we can assume with good reason that some mechanism limits the organism to thinking about one thing at a time. Perhaps a more important analogy between the computer and the human is to be made at the programming level. Obviously, at the hardware level, there are gross differences. However, we can make a convincing case (see Miller, Galanter, & Pribram, 1960) for picturing thinking as a complex computer program.

Learning consists of building appropriate subroutines to handle special tasks. These subroutines are combined appropriately by some central processing program which (1) monitors input, (2) stores tasks to perform and data to act upon, (3) sets priorities, and (4) controls output.

An exact definition of information-processing theories (IPT) is difficult to formulate. The fundamental premise is that learning consists of establishing elementary processes for manipulating symbols. In general, an encoded stimulus is treated as a set of information-carrying components. The subject is presumed to analyze, compare, and organize these components. Then decision rules that compare past information input and outcome contingencies with the state of current input components are used to determine the next response. In contrast to mathematically stated theories or verbally stated theories, most information-processing theories are stated in the language of a computer program. This does not necessarily mean that the theory in any way resembles a computer or a computer program. In fact, as we shall see, it can be simply a way of realizing a verbally or mathematically stated theory.

Another feature of IPT is the tendency to incorporate into them heuristics or rules of thumb that are helpful in learning or problem-solving. Heuristics do not guarantee a solution to a problem but often help in finding the solution. An example of a heuristic, used by Hunt et al. (1966) in their concept-learning system (CLS), is the division of the set of presented stimuli according to the value that occurs most frequently in the set of correct stimuli (see step 3 of Hunt et al. p. 967).

Reasons for using information-processing theories Most advocates of IPT would argue that they have turned to IPT because IPT more closely resemble the "true" state of affairs. (But IPT are of course by no means in any unique position with respect to truth or correctness of interpretation.) IPT are usually relatively complex and dynamic. Certainly all of human learning has not been satisfactorily described or explained by any existing model, mathematical or verbal. Thus, it is argued, because IPT represent more facets of the total behavior, they are more realistic. Another reason for introducing IPT is that mathematical and verbal analyses have not been powerful enough as tools and, presumably, the language of the computer is more powerful. This is probably true in the sense that complex interactions and nonlinear relationships can be stated in computer programs, and, by simulation, some indication of the results of these interactions can be obtained. Another advantage of the IPT is that one may compute some statistic on the data and wish to know what a particular theory would predict for that statistic. It may be impossible to derive the statistic formally but a rough idea of its value can be obtained from simulation of the IPT. Furthermore, IPT are often broad and general in scope and not procedure-specific. For example, the General Problem Solver (GPS) makes no specific reference to the subject matter of the problem to be solved. The approach taken is to (1) set up goals, (2) transform goals so that operators can be applied, (3) apply operators, and (4) look for differences to reduce by some operator. Newell, Shaw, and Simon (1958) and Newell and Simon (1961, 1963) have presented the details of this program. IPT are superior to verbally stated theories because they must be stated exactly and consistently. Although inconsistent statements may survive in verbally stated theories because a proof of their inconsistency may be difficult to derive, this is not possible in an IPT stated as a computer program. If indeed an inconsistent theory can be programmed at all, it will always fail to operate at some point. Thus, stating a theory as a computer program can be worthwhile for this reason alone.

Problems with using information-processing theories Programming a computer is costly and difficult. Further, stating a theory

as a computer program limits the accessibility of the theory, and thus the number of researchers working with it, because not all researchers have easy access to computers. (These points are certainly becoming less valid with modern computers.) Another problem with IPT is that they are usually complex and have built into them a number of hidden assumptions. This, of course, is related to their ability to deal with more complex processes. However, it means that, in testing the theory, we are testing a total complex structure. If it proves to be inadequate, it is difficult to say exactly how or where it is inadequate. Perhaps the most serious problem with computer-stated theories is that of testing them. Because we do not have exact mathematical statements, parameters are difficult to estimate. We do not obtain theoretical expressions but only the results of simulation. Thus, we generally do not try to test the theories exactly (as with a chi-square goodness-of-fit test, for example), but rather qualitatively: Do the results correspond in general with the observed results? These difficulties are mentioned in order to insure that a fairly realistic appraisal of IPT be made by the reader.

Concept-learning information-processing models To date, there have not been many IPT for concept learning, nor have they been responsible for generating many experiments. However, they are rapidly becoming more numerous and more sophisticated. Therefore, it is necessary for us to review, albeit briefly, the current approaches using IPT.

The first IPT, discussed by Hunt and Hovland (1961), contains five basic subsystems for data processing. The first subsystem determines what aspect of the stimulus is encoded and put into memory. The second is the memory storage system.

Two versions of memory storage are considered: finite memory with serial input and infinite memory; these correspond to the reception and selection presentation procedures. The core of this IPT lies in the "answering developing routine," which in many ways is similar to the CLS system discussed earlier (CLS-1). There is an executive routine which orders the calls of four basic routines. One of these basic routines is the ordering routine, which separates items into mutually exclusive and exhaustive subsets, thus accomplishing essentially what steps 1, 2, and 3 of the CLS-1 system do. The second basic routine, the solution routine, looks for particular logical relationships that account for the order determined by the ordering routine. The usual procedure is to consider conjunctive routines first and then disjunctive routines. The third basic routine, the descriptive routine, looks for alternative descriptions on which to make comparisons. In its simplest form, this routine amounts to finding a new set of dimensions to consider in the ordering and solution routines. However, it can also mean finding relational characteristics of the stimuli (for example, "larger," "smaller"). Finally, there is a time-checking routine to limit the time spent on each of these processes. Because subjects cannot do all this processing without taking time, and because, in many cases, stimuli are presented too fast for a complete check to be made, the time-checking routine halts processing and makes the subject return to the executive routine to initiate the processing of a new stimulus.

The final two major routines in the information-processing routine discussed by Hunt and Hovland are the answer-checking routine, which simply checks the simulated subject's answer with the answer determined by the experimenter, and the transfer routine, which considers what sort of transfer one problem should have on another. Little is known or even speculated about the details of this latter routine except that certain transfer functions, such as carrying over the same solution system to the next problem, seem obvious.

This brief description should indicate some of the problems with specifying *in toto* a theory of concept learning. For example: How does one specify the order in the ordering

routine? The times for each part of the processing unit? The particular solutions in the solution routines? What variables influence the kind and order of descriptions subjects will attempt to use?

Hunt, Marin, and Stone (1966) have introduced a more systematic investigation of concept learning. Instead of beginning with a very complex structure as Hunt and Hovland did, they begin with some simple models and gradually change them to see what effect each change brings about. They are interested not only in developing a theory of human concept learning but also in developing an artificial intelligence system, that is, a program to solve concept problems not already solved by humans. Examples of the latter include content analysis, in which verbal documents are coded according to a set of variables (dimensions and values as usual); the variables are then read into the program in order to see if a structure can be developed that will "solve" the problem. Hunt et al. apply their programs to such diverse topics as suicide notes, the California Money Bill, biographies, and medical statistics. The second general area of application of the general CLS program is *pattern recognition.* Although pattern recognition seems rather far afield from concept learning, Hunt and his associates show how closely the concepts and problems in these two areas are related. (See also Uhr, 1966.)[7] Hunt et al. have studied 10 versions of the concept-learning system (CLS); we have already introduced the simplest version. CLS-2 and CLS-3 add a limited memory to the system. The general conclusion is not necessarily intuitive: With limited memory systems, the number of items needed to solve concept problems increases but the amount of computing decreases, and the latter effect offsets the former. The CLS-4 and CLS-5 models were developed for the selective-sampling procedure as opposed to the receptive-presentation scheme. The basic heuristic used was to select stimuli at random until an error was made, at which point stimuli "close to the error stimulus" were selected. CLS-6 introduced a substitute for step 3 discussed earlier (see p. 967). Instead of counting the most frequent value on positive instances, CLS-6 computed the value with the largest difference between positive and negative instances. Thus, if red objects occurred with positive stimuli 10 times and with negative stimuli 2 times, the difference $10 - 2 = 8$ was computed. The stimulus value with the largest difference was used to sort the items. These examples should be sufficient to illustrate the nature and ideas behind this approach. For further information about work in this area see Hunt (1967) in which CLS-10 is developed and discussed.

We noted above that Trabasso and Bower (1966) could not solve explicit equations for the various statistics of their extended model; thus, they simulated the model. The extended model can be considered an information-processing model. A similar approach was used by Gregg and Simon (1967), who began with the basic ideas of the cue-selection model and extended it by introducing assumptions about the nature of hypothesis sampling. Their point is that their IPT is more general and encompasses the cue-selection model as a special case. Essentially they have taken general ideas that have appeared in the literature mostly in verbal form and have developed a model for them. Gregg and Simon suggest three alternative sampling schemes: (1) *local nonreplacement,* in which

[7]The point to be made here about artificial intelligence is that it is important to our conceptualization of concept learning. Too often perhaps, the solution to a problem is attempted in the most direct manner possible. An experimental psychologist wishes to know how concepts are learned and immediately starts to run experiments. The approach of artificial intelligence is to put aside the direct behavioral question of how humans solve problems and consider first the broader question of how problems can be solved in general. If a sufficiently general theory is formulated, the question of how humans solve problems might possibly be answered simply by picking the approach that best describes their behavior. Of course, artificial intelligence provides no philosopher's stone for understanding human behavior. Indeed, in certain fields, for example, pattern recognition (Uhr, 1966), the most powerful computer programming techniques developed so far perform more poorly than humans. Probably when human behavior is better understood more powerful techniques will be available.

the hypothesis rejected on trial *n* is not returned to the pool of hypotheses from which the subject samples, (2) *local consistency,* in which the pool of hypotheses from which a subject samples after an error is limited to those hypotheses consistent with the last presented stimulus, and (3) *global consistency,* in which the pool of hypotheses from which a subject samples after an error is limited to those hypotheses consistent with all stimuli presented previously. In line with the cue-selection theory of weighting the various dimensions according to their saliency, Gregg and Simon note that all the alternatives above can have unequal hypothesis-selection schemes.

As Gregg and Simon point out, one advantage of the IPT approach over the mathematical approach is a more complete statement of the theory. Many qualifications about the applicability of the cue-selection model were made by Bower and Trabasso because the mathematical version they developed incorporated a fixed set of assumptions appropriate only to the situation they studied.

Other IPT for concept learning have been introduced. A particularly interesting one is by Simon and Kotovsky (1963). The concept-learning task does not fit into the scheme we have described here, but, because that scheme is not appropriate to all concepts, perhaps a slight shift at this point will indicate some of the possibilities not touched on in this section. If you were presented with a sequence *abababab* . . . and asked to continue it, most people would continue the pattern and write *abab*. . . . Although, mathematically, any sequence of finite length can be extended in any manner whatsoever, a given pattern usually restricts the type of continuation patterns that most subjects will give. There seems to be a set of rules that almost all subjects follow to determine the pattern which is presented. The universality of these rules allowed Simon and Kotovsky to study the ease of finding consistent patterns in sequences such as the example above. Simon and Kotovsky attempt to include in a process model the rules that subjects use and to see if the model will simulate the performance of human subjects. They assume that subjects come into the task with the following generative rules and processing abilities: (1) the English alphabet and its sequential order, (2) the English alphabet in its backward order, (3) the concept of "same" or "equal," (4) the concept "next" on a list, (5) the concept of a "cycle," a repetition of a fixed sequence, (6) a small memory for symbols. They then derive a model for searching for patterns in sequences such as *abmcdmefmghm* . . . , stating the patterns discovered as generative rules, and extrapolating the pattern. The theory rank-orders the difficulty of sequences and is in good agreement with the rank order determined by subjects.

PAIRED-ASSOCIATE AND SERIAL LEARNING

Paired-associate learning (PAL) and serial learning (SL) are the two most widely used experimental procedures in human learning. They appear to tap directly fundamental processes and provide a natural and convenient vehicle for the study of verbal behavior. They are rivaled in these respects only by free-verbal learning (see Chapter 19). Underwood (1964) characterizes rote verbal learning as consisting of four tasks: free-verbal learning, serial learning with or without syntactical ordering of units, verbal discrimination, and paired-associate learning. He argues that these tasks are central to all human learning. However, other aspects of human learning seem to be neglected in Underwood's analysis. For example, Underwood is reminded by Wickens (1964) that motivation is conspicuously absent in the field of rote learning. Also, there seem to be some differences between verbal learning and traditional motor learning, although a good case can be made that very similar processes are involved in both (see, for example, Fitts, 1964). Because of space limitations, we shall not discuss motivation, motor

learning, or all of the four tasks of verbal learning. Instead we shall limit the discussion to the two specific verbal-learning procedures of PAL and SL.

A great many of the studies in verbal learning have been concerned with the measurement of relationships between verbal items. Although we shall be interested in how subjects encode stimuli in order to respond correctly in PAL and SL, we shall not discuss the many experiments that have investigated various similarity measures of verbal stimuli such as meaningfulness, associative strength, or relative frequency.[8]

Another class of studies has been concerned primarily with transfer of training, distribution of practice, incidental learning, and interference effects. This class is covered in Chapter 21.

Historical Background

In current terminology, studies in PAL and SL deal with connections between stimuli and responses. However, such connections were formerly referred to as "associations." The notion of associationism goes back to Aristotle, who emphasized the importance of three factors in the formation of associations: contiguity, similarity, and contrast. In the past 60 to 80 years, every major psychological theory has in some way modified and shifted the work in verbal learning. We shall not trace this development, but recommend earlier works (Robinson, 1932; Woodworth, 1938; Woodworth & Schlosberg, 1954; and McGeoch & Irion, 1952).

Prior to 1940, most studies concentrated on serial learning, although in the last 15 years there have been many more PAL studies than SL studies, and the general consensus is that SL is more complex and less useful as a basic paradigm for the study of how associations are learned. Ebbinghaus (1885) studied SL extensively and many of the basic phenomena of serial learning were discussed by him, whereas PAL was first recognized clearly in an article by Gibson (1940). A psychologist in 1940 may have felt that serious quantitative theorizing was about to begin in serial learning with the publication of *The Mathematico-Deductive Theory of Rote Learning* (Hull, Hovland, Ross, Hall, Perkins, & Fitch, 1940). However, the lack of parsimony in the Hull et al. theory has negated its precision. In any case, these two publications provided the fundamental analysis of PAL and SL that has dominated theoretical research since 1940. The last 10 years has seen a flood of experiments that have illustrated many shortcomings in the earlier theoretical approaches, but, as yet, no comprehensive theory has been substituted for them. Our discussion here describes the traditional approach, samples a number of research studies which are detrimental to it, and presents some recent alternative theoretical approaches.

[8]Chapter 19 describes and analyzes such measures.

Basic Paradigms

There are two basically different procedures for both PAL and SL. One is the *anticipation method* of presentation and the other is the *reinforce-test* or *study-recall method* of presentation. In the paired-associate paradigm, a list of N stimulus-response pairs is presented to the subject, who is explicitly instructed to learn to recite the response when presented with the stimulus. In the anticipation method, the stimulus of the first pair is presented and the subject is expected to make the appropriate response. Many recent studies have violated the condition that the time to respond be fixed. Traditionally, the stimulus item was presented for a fixed time (usually a few seconds) during which the associated response was to be made. Naturally, with short intervals, there are many more trials without responses than when more flexible time limits are employed. Whether fixed or flexible periods for responding are provided, almost always the response item is exposed for a fixed period following the subject's response. Then, after an interitem interval, the next stimulus item is presented. The stimuli are all presented and, except when the effects

of serial presentation are of explicit interest, the items are randomized before the next trial. In the reinforce-test procedure, all S-R pairs are presented randomly, one pair at a time. The next trial is then a test trial on which only the stimuli of the S-R pair are presented one at a time in a new random order. Of course, there are many possible variations on this procedure, some of which will be mentioned later.

The PAL task may be thought of as consisting of three psychological processes. The first process is that of discriminating the various stimuli one from the other (Gibson, 1940). The second process is that of learning the responses themselves, which is basically a free-verbal recall task. In order for the subject to give the response, he must know it. The typical PAL experiment often uses a list of nonsense syllables for responses and such a list may require quite a few trials to be learned. Finally, the third process is that of associating each stimulus with its appropriate response.

In serial learning, the subject learns a list of stimulus terms in the order in which they are presented. Under the anticipation procedure, one item is presented and provides the stimulus for the next, which in turn becomes the stimulus for the third item. Although this description seems to emphasize the similarity between paired-associate learning and serial learning, many investigators doubt that we can look at SL as a chain of S-R paired associates. In the reinforce-test procedure, the list is presented and then the subject is asked to repeat it exactly as presented.

It should be emphasized that there is no right or wrong procedure per se. One reason for many of the variations in procedure is that each different procedure allows us to investigate a different aspect of the problem. Of course, procedures differ due to the different underlying psychological processes involved and in the different strategies that subjects will use in trying to learn what is asked of them. At the present time, there is no theory sufficiently general to describe all the processes involved or the strategies that will be used, although such a general theory is a central goal of studies in PAL and SL.

No discussion of PAL and SL, or any other rote-learning procedure for that matter, would be complete without mention of the memory drum (see p. 853). In most PAL and SL experiments, the list is presented on a memory drum, which has the advantage that the presentation of stimuli can be timed precisely. (Early emphasis on the idea that rote learning was an extension of conditioning theory made such strict control of time important in learning studies. Recent experimental results have raised questions about strict pacing since such pacing may produce fluctuations in stimulus selection.) In an alternative procedure the subject is allowed to determine when the next stimulus is to be presented; that is, he is allowed as much time as he wants in which to respond. In either case, the subject himself has a certain amount of control over the actual learning procedure. With the memory drum, the subject may pick a few stimuli to rehearse and let others go by. With the self-paced procedure, the subject can repeatedly rehearse an item, so that there is no control over what constitutes a trial. In any case, timing factors are crucial in both PAL and SL. Obvious independent variables to be determined include the time the stimulus is left on, the time allowed for a response to be made, the time between the response (or stimulus) and the next stimulus presentation, and the time between trials (complete repetitions of the list). Some of these can be fixed by the experimenter, some by the subject only, and some by both the experimenter and subject.

Perhaps the other general variable of most interest is the nature of the stimulus and response material. Traditionally, studies have usually used nonsense syllables (CVC) or consonant clusters (CCC) as stimuli and responses. But words and visual nonverbal stimuli have also been used. If CVCs or CCCs are used, the appropriate response is usually a spelling out of the letters. If words are used, a simple oral response is most common. Some

studies have required the subject to make a motor response such as pushing one or more buttons. If visual forms or motor responses are used, Underwood (1963) questions whether the learning should be called verbal. Nevertheless, the predominant response to any stimulus is verbal, for most subjects number or name their responses.

There is a large literature concerned with how to organize stimuli to account for their role in determining the difficulty of learning. That is, a variety of scales have been devised that correlate with the difficulty of learning. Perhaps the first consideration of the correlation between learning and the stimulus material was made by Ebbinghaus (1885). He theorized that, because words are meaningful, they are highly associated with each other, and learning involving words is therefore partially a function of past learning. Ebbinghaus' idea was to begin with new material, the nonsense syllable. At this level of analysis, there is no doubt about the results: CVCs and CCCs are more difficult than words. But nonsense syllables also differ one from another. Thus, Glaze (1928) scaled nonsense syllables according to the percentage of 15 subjects who had an association to each nonsense syllable within 3 seconds. Archer (1960) redid Glaze's list for CVCs and Witmer (1935) applied Glaze's method to CCCs.

Of course there are other ways to scale such materials, many of which are described in Chapter 19. Noble (1952) asked his subjects to write all the associations they could think of. More recently, Noble, Stockwell, and Pryer (1957) had subjects simply rate the association values. Underwood and Schulz (1960) considered pronunceability, and Noble (1953) had subjects rate familiarity. Finally, the frequency with which subjects have experienced the stimuli may be determined by such measures as the relative frequency of the clusters or letter pairs in the language. All these scaling procedures have correlated positively with learning rate. However, Underwood and Schulz (1960, p. 86) feel that this is because all such scales are actually measuring the past frequency of use or experience with the item. They posit a basic hypothesis, the *spew hypothesis,* which states that "the order of emission of verbal units is directly related to frequency of experience with those units."

Relationships between Procedures

Whether or not there are fundamental psychological relationships between the PAL and SL procedures and the PL and CL procedures is still very much a matter of debate. For the most part, psychologists try to stay with a single theoretical structure and apply it differently for different procedures. Thus, in the discussion of PL presented here, statistical learning theory is emphasized, but recent studies that have raised serious doubts about its applicability are mentioned. In the discussion of CL, a cue-selection theory was emphasized, but much of the early work treated CL as a form of discrimination learning. Similarly, in PAL and SL, the predominant theoretical position has been to consider these procedures from a conditioning and/or mediation point of view. However, as we see below, there are other views and we cannot choose one theoretical explanation to the complete exclusion of others.

There are some close relationships between the four tasks in terms of procedure. For example, if a list of length N in PAL is composed of r responses, where $r < N$, then, in terms of the procedure, we potentially have a CL experiment. The difference depends on the existence of a rule assigning the stimuli to the response classes. But if the subject does not yet know the rule, he may learn the associations as in a PAL procedure. On the other hand, if there is only one stimulus and two responses, or if each response is probabilistically associated with each of the stimuli, then, for a single trial or more when a single stimulus and response are consistently paired, a PAL procedure is in effect. One much-discussed procedure in PAL is the "S-R_1 followed by S-R_2" paradigm, in which first the R_1 response is learned to the S stimulus and then the R_2 response is learned to the same

stimulus. Except for the extent of learning, this procedure looks a great deal like the learning that occurs in PL. Finally, in SL, there is the problem of integrating responses over time. Although the traditional SL procedure has involved a different stimulus for each unit in the series, if only two or three units were used, we would have the procedure investigated by Keller (1963) and Restle (1966) in which a fixed binary sequence was repeated over and over. As yet not enough work has been done on such relationships, for different theoretical questions and techniques of analysis are used for the different designs. Probably the most common manner of relating the designs is to begin with a theoretical structure and to consider how it applies to each procedure.

Traditional Theoretical View of Rote Learning

Many researchers in human learning have avoided theoretical speculation and have considered themselves functionalists. Nonetheless, there is an underlying theoretical view which stems from Pavlovian and Hullian theory and from extensions made by theoreticians during the late 1930s, 1940s, and 1950s. A number of surveys of this system are available (see, for example, Koch, 1954; Kimble, 1961; Hilgard & Bower, 1966), so we merely summarize at this time.

The central idea in Hullian theory is habit strength, which is the strength of a bond between a stimulus and a response. This bond is assumed to be strengthened each time the stimulus and the response are paired and the response is followed by a reinforcer. The functional relationship is a familiar one, a negatively accelerated growth function with asymptote H_∞, initial value H_1, and learning rate α (see Equation 10).

$$H_n = H_\infty - (H_\infty - H_1)\alpha^{n-1} \qquad (53)$$

We shall not discuss here all the variables which control H_∞ and α because these represent applications of the theory. However, it is important to emphasize that the probability of a response is not directly related to H_n. H_n represents learning; however, performance, as measured by the probability of a response, the latency of a response, the magnitude of a response, and so on, is derived from H_n and a number of other variables. The variable which is important in determining these performance measures is called *excitatory potential, E.* Excitatory potential is a function of H_n and other factors; that is,

$$E = F(H_n, L, O_t, I_n, D, \ldots)$$

In turn, response measures such as the probability of a correct response are related to E by other functions specific to the measures themselves,

$$G_p(E) = G[F(H_n, L, \ldots)]$$

We shall discuss only some of the major variables.

In animal learning, drive (D) is a central concept of Hullian theory; in human learning, a more important concept is threshold L. Although learning may be going on, no measure of it can be made until it has reached and exceeded threshold. Further, various dependent variables, such as recognition and recall, may have different thresholds. But for any one measure, until H_n exceeds the threshold for that measure, there is no change in performance.

Another important Hullian concept is oscillation O_t. The discussion above might lead one to believe that once H_n exceeded threshold, the subject would always perform correctly. However, the theory also assumes that many factors tend to inhibit and reduce performance below optimum levels. These factors, which vary from trial to trial in a nonsystematic way, are referred to as the oscillation of inhibition. Hull assumed that these inhibiting factors subtracted from the H_n factor and that they were normally distributed.

Finally, there is the concept of conditioned inhibition I_n. Each time a stimulus-response bond is not reinforced, a negative factor tends to prevent the stimulus from eliciting the

response which has been built up (Spence, 1956, p. 120). In general, $I_{n'}$ is assumed to accumulate in a manner very similar to H_n, except that it changes only on nonreinforced pairings:

$$I_{n'} = I_\infty - (I_\infty - I_1)\beta^{n'-1} \qquad (54)$$

when n' is the number of nonreinforced trials. The terms described above can be combined to describe various aspects of learning.

One difficulty in dealing with the normal-curve assumption for oscillation is that the normal curve is a continuous distribution from $-\infty$ to $+\infty$, but because the oscillation of inhibition always subtracts from H_n, it is necessary to assume some arbitrary point on the normal curve to call the point of zero subtraction. Hull usually assumed a point at 3 or 4 standard deviations. A second difficulty in dealing with a normal curve is that, to compute the probability of a response, the normal curve must be integrated. Tables are used for such evaluations. We assume that we can roughly approximate the normal distribution of the oscillation function with a uniform distribution $y = x/\delta$, where δ is the range of the oscillation function $(0 \leq x \leq \delta)$. First, until H_n exceeds the threshold value γ, no response can be made. After H_n exceeds γ, the probability depends upon the portion of the uniform curve which exceeds γ; that is, $H_n - \gamma$. If $H_n - \gamma$ is greater than δ, the probability of a response is 1.0. From the point where $H_n = \gamma$ until $H_n > \gamma + \delta$ the curve rises directly with H_n. Figure 20.13 illustrates such a function. If we used the normal curve for oscillation, the probability curve would rise slowly at first, then rapidly, and then slow down again—an ogival-shaped function. It is important to note that, in addition to the initial habit strength H_1 and the asymptote of habit strength H_∞, δ, γ, and α must be estimated as well. If conditioned inhibition is important, I_1, I_∞, and β must be added to the list of parameters to be estimated. The function also depends upon the form of the oscillation function, which has historically been chosen arbitrarily. However, the drawbacks to postulating so complex a function are perhaps outweighed by the versatility of the function. The "silent period" when habit strength is changing but no responses occur can be used to explain why one reinforcement does not always lead to some performance change. During the so-called "overlearning period" after perfect performance is reached, reinforcements can be used to increase the strength of a habit, an increase that might be measured by noting the number of trials needed to produce extinction or counterconditioning.

Figure 20.13. Schematic representation of a Hullian-type model. To make calculations easier, the oscillation $O(x)$ is assumed to be uniformly distributed rather than normally distributed.

When Gibson introduced the notions of Hullian theory to paired-associate learning in 1940, the above-mentioned tripartite conception of paired-associate learning had not been formulated; simple classical conditioning ideas predominated. Gibson's main contribution was to emphasize that a principal source of difficulty in PAL was that of differentiating the stimuli. Thus, each stimulus and response should develop some habit strength connecting them, but if two stimuli were similar, the habits would interact to produce error responses. Consider, for example, stimulus-response pairs, $S_1 - R_1$ and $S_2 - R_2$. To each is associated a habit strength, H_{11} and H_{22}, respectively. But if S_1 and S_2 were similar,

there would also be an $S_1 - R_2$ (H_{12}) habit strength built up and an $S_2 - R_1$ (H_{21}) habit strength built up. This would be due to primary generalization between S_1 and S_2; that is, the degree to which H_{12} and H_{21} developed would depend upon the similarity between S_1 and S_2. The analysis proceeded as follows. At first, all *H*s were below threshold, so that when S_1 or S_2 was presented, the subject could not respond. Thus, early in learning the subject did not respond (omissions occurred). Later, *H*s were above threshold and responses occurred. When S_1 was presented, because of H_{11} and H_{12} habit strengths, both responses R_1 and R_2 tended to occur in a ratio depending upon their relative strengths. This competition among responses produced random-like sequences of R_1 and R_2 responses. However, whenever R_2 occurred to S_1, it was not reinforced, and the lack of reinforcement led to the development of conditioned inhibition. Conditioned inhibition, like the inhibition of oscillation, subtracted from the H_{12} habit strength, so the excitatory potential for R_2 diminished. The R_2 response weakened while the R_1 response increased in strength. This was the discrimination process. Finally, only H_{11} and H_{22} remained strong and uninhibited. An intertrial interval allowed spontaneous recovery of the inhibited H_{12} and H_{21} habits. So after a rest interval, confusion errors reoccurred. Continued discrimination training finally built up permanent inhibition of the H_{12} and H_{21} habits.

Gibson's discussion of the similarity between stimuli was for the most part tied to the physical characteristics of the stimuli, although she did not state any rules for the measurement of similarity. In his review of Gibson's thesis, Underwood (1961) notes that the notion of similarity allows generalization along a semantic or meaningfulness scale to be easily included in the scheme. In fact, most tests of her theory have used this dimension of similarity. Gibson stated many more implications of this way of looking at PAL, but since most of them are concerned with transfer phenomena, they will be covered in Chapter 21.

When applied to serial learning, the Hullian formulation of conditioning processes was more rigorous (see McGeoch & Irion, 1952). A serial-learning experiment yields one result, the serial-position curve, which is unique to the procedure. If the number of errors made in learning each item is plotted against the position of the item in the list, a bow-shaped curve results. For example, a list of six items might yield 1, 3, 10, 25, 10, and 3 errors for items in positions 1 through 6, respectively. Note that the maximum number of errors is just beyond the middle of the list (at position 4). The ability of a theory to explain and predict this function was considered of primary importance in evaluating the theory. The Lepley-Hull theory, developed specifically to handle the serial-position effect, made the following assumptions. First, SL consists of a series of stimuli, S_i, $i = 1, 2, \ldots n$, presented repeatedly in the same order. Each stimulus leaves a trace that persists over time; thus, when S_i is presented, the stimulus consists of not only S_i but also $S_{i-1}, S_{i-2}, \ldots S_1$ to varying degrees. Furthermore, because of the facts of trace conditioning, when S_j occurs, it is connected as a response (that is, some habit strength develops) to S_i, $i < j$. The larger the distance between i and j ($j - i$ distance), the smaller the habit strength. In order for the stimulus S_i to evoke S_{i+1} and only S_{i+1}, the associations to S_{i+j}, $j = 2, 3, \ldots$ have to be suppressed by the conditioned inhibition process. With a list of length n, S_1 has $n - 2$ inhibitions to establish so that only S_2 occurs to S_1. When S_2 occurs, the stimulus consists of the trace of S_1 and S_2. There are $n - 3$ inhibitions for S_2 and $n - 3$ for S_1; that is, $2(n - 3)$. In general, the sources of inhibition for making the ith response to stimulus $i - 1$ are $(i - 1)(n - i)$. The resulting number of inhibitions for a 6-item list are: 0, 4, 6, 6, 4, 0. The displacement beyond the center point in the error curve is produced by other factors in the Hullian model. A virtue of the Lepley-

Hull theoretical scheme was the close contact it made with the basic theoretical processes assumed to be occurring in classical conditioning. Hence, a complex human-learning situation was analyzed and explained by these basic psychological mechanisms.

The description just presented is by no means complete, and is therefore to some extent unavoidably misleading, but it should give the reader some idea of the predominant interpretation of learning in PAL and SL up to 1950. Later in this chapter we emphasize some opposing views and how they contrast with the Gibson and Lepley-Hull descriptions. We begin by considering some alternative theoretical views of the acquisition process itself. Later we return to questions about stimulus confusions and response learning.

The All-or-None Theoretical View

Empirical basis The standard statistical way of indicating that learning has taken place or is taking place is to present a learning curve. In general, any average measure of performance (percentage correct, average number of correct responses, decreasing number of errors, and so on) shows a gradual change over trials. This result is so common that it has been accepted as fundamental and has provided the rationale for the linear operators discussed earlier and the change in H_n we have just derived. However, in going from the observed performance curve to statements of fundamental process, an important caveat mentioned earlier has been ignored. The performance curve is an average curve. Many functions can yield an average curve, although they themselves are not of the same form as the average. We can easily make the mistake of inferring a fundamental process from an average curve instead of considering some process for the individual and deducing what the average curve would be according to that process. If the theoretical average agrees with the observed average, we have support for the assumption about the individual function—but have not proved it. Of course, the inference that learning is a gradual process is not based solely on the learning curve. Many other facts about learning seem to lead to the conclusion that each reinforcement produces a small increase in the S-R bond. Nonetheless, a number of situations suggest a different function. In the animal literature, the Krechevsky-Spence controversy over whether animals test hypotheses has raised the issue of the learning function. In operant conditioning, an animal will often suddenly start responding at what seems to be a terminal rate. In avoidance situations, an animal may make his first avoidance and then never again fail to avoid. In the human learning situation, elementary laboratory instructors often find subjects who learn a serial or paired-associate list in one trial. Do these instances represent cases of fast learning rates, chance occurrences, or do they suggest that the assumption of gradual change in learning is not always correct?

Rock (1957) and Rock and Heimer (1959) ran a series of experiments that raised serious questions about the incremental learning process. A list of stimulus-response pairs (double letters or nonsense syllables paired with 2-digit numbers) was presented for 3 sec with a 5-sec interval between pairs. After the presentation of the complete list, a test trial was given on which only the stimuli were shown, again one at a time. All items for which a subject gave an incorrect response were removed from the list and new items were added for later trials. Rock argued that if there was a gradual increase in associative strength, then, by removing items, the learning process would be slowed down because all missed items would have to start again at the H_1 strength of association. The necessary control group did not have error items removed. Rock found no difference in the learning rate of the control and experimental groups. If items were learned all at once, or on a single trial, then these results would be easily explained.

Although the experiment is provocative, there are several problems associated with it.

Clark, Lansford, and Dallenbach (1960), Underwood, Rehula, and Keppel (1962), and Postman (1962, 1963) raised a number of questions about the Rock procedure of eliminating error items. The first objection concerns the slow rate at which the stimuli were presented. If the stimuli are presented slowly, subjects can rehearse a given pair of items many times. This criticism raises the question of what constitutes a trial. The usual procedure is to present items for about 2 sec with 2 sec between items. In replicating Rock's experiment, Clark et al. found that if stimuli were presented for 1 sec each with no interval between items, the control group was poorer than the experimental groups. However, because others have found the reverse, rate factors as such are not clearly related to the Rock effect.

A second objection, and one with substantial support, is that, under Rock's procedure, the list of items learned by the experimental group is an easier list. The items thrown out, on which errors were made, are prima facie more difficult than those left in the list. There are a number of arguments supporting the contention that the lists are not of equal difficulty. One argument concerns individual or idiosyncratic factors that make items easier or more difficult for different subjects. It seems nearly impossible to isolate such factors, and insofar as they exist, they make the Rock procedure difficult to control. Also related to the difference in difficulty of the items remaining in the experimental list and in the control list is the role of interference. Certain items might interfere with each other; this would lead to errors and the elimination of the confusing items. Eventually a less confusing list for the experimental subjects would result. Intralist interference is certainly known to play an important role in paired-associate learning (see Chapter 21 for additional material). Third, as Postman points out (1962), in some of Rock's experiments, the subjects had to learn responses as well as stimulus-response bonds. Postman argues that two learning processes would not, in general, yield all-or-none learning. Interestingly enough, Kintsch (1963) has used the argument that two learning processes exist in the Rock experimental design to support all-or-none learning. By using a 2-step model, Kintsch explains the differences that he observed between control and experimental groups in this design. He assumes that response learning and an association process are involved. These arguments certainly leave the all-or-none vs. incremental learning question unanswered. It appears that the particular experimental design used by Rock is not ideally suited to provide unambiguous results.

The RTT design In a series of papers and associated experiments, Estes (1960, 1961, 1964a), Estes, Hopkins, and Crothers (1960), and Izawa (1966, 1967) probed the all-or-none learning question more deeply. Let us assume for the purpose of derivation and simplification that we have a set of homogeneous subject-items.[9] The reinforce-test trial procedure is used in the RTT design, and it is assumed that test trials are neutral; that is, no change is made in the stimulus-response bond on trials when a subject has to respond to a stimulus with no feedback concerning whether or not he was correct. Now, if learning is incremental, then, when each item is reinforced, the S-R bond increases in strength. Assuming homogeneous learning rates, and all S-R bonds at zero before reinforcement, then after one reinforcement, all items will have the same probability α of a correct response. If we give a test trial with N subject items, then, on the average, αN of them will be correct. Estes (1961) asked the simple question: What proportion of the items correct on the first test trial will be correct on a second test trial? Thus the design was RT_1T_2, with R being one reinforced trial, and T_1T_2 being two test trials. Let us designate the correct and error items by C = correct and E = error, with a sub-

[9] If there are M subjects, each of whom receives N stimulus-response items, then there are $M \cdot N$ subject items. A subject item is any stimulus-response pair from any subject.

TABLE 20.6 ALL-OR-NONE AND INCREMENTAL PREDICTIONS FOR THE RT_1T_2 DESIGN

		All-or-none model		*Incremental model*			
Outcome for test trials	*Observed results*	*Simple*	*Forgetting*	*Simple*	*Individual difference*	*Retention differences*	*Test-trial learning*
C_1C_2	.238	α	$\alpha\beta$	α^2	$\frac{\Sigma\alpha_i^2}{N}$	$\frac{\alpha\Sigma\beta_i}{N}$	$\alpha[(1-\beta)\alpha+\beta]$
C_1E_2	.147	0	$\alpha(1-\beta)$	$\alpha(1-\alpha)$	$\frac{\Sigma\alpha_i(1-\alpha_i)}{N}$	$\frac{\alpha\Sigma(1-\beta_i)}{N}$	$\alpha[(1-\beta)(1-\alpha)]$
E_1C_2	.017	0	0	$(1-\alpha)\alpha$	$\frac{\Sigma(1-\alpha_i)\alpha_i}{N}$	$\frac{(1-\alpha)\Sigma\beta_i}{N}$	$(1-\alpha)(1-\beta)\alpha$
E_1E_2	.598	$(1-\alpha)$	$1-\alpha$	$(1-\alpha)^2$	$\frac{\Sigma(1-\alpha_i)^2}{N}$	$\frac{(1-\alpha)\Sigma(1-\beta_i)}{N}$	$(1-\alpha)[1-(1-\beta)\alpha]$

script 1 or 2 for the test trial of interest. Each item must fall into one of the four classes: C_1C_2, C_1E_2, E_1C_2, and E_1E_2. According to an incremental model, α^2 should be in the C_1C_2 class, $\alpha(1-\alpha)$ in the C_1E_2 class, $(1-\alpha)\alpha$ in the E_1C_2 class, and $(1-\alpha)^2$ in the E_1E_2 class. In a number of experiments, to be discussed more thoroughly below, Estes found this not to be the case. Items correct on the first test trial tended to be correct on the second, and items wrong on the first test trial tended to be wrong on the second. One possible explanation is that items are learned in an all-or-none fashion. The all-or-none theory would say that a proportion α of the items were learned, and a proportion $1-\alpha$ were not learned. Then the four outcome classes would have probabilities α, 0, 0, and $1-\alpha$. Although this pattern of results was not obtained exactly, the pattern of results was closer to the all-or-none version than to the incremental version. The logical next step is to see what restrictions or assumptions are most likely to be responsible for the deviations from the theories.

To account for the observed results, Estes (1961) considered three possible variations in incremental conditioning. Estes used consonant trigrams as stimuli and English words as responses. Because the subjects did not know the words beforehand, the initial probability of a correct response was zero. The RT_1T_2 design was used, yielding the values .238, .147, .017, and .598 for the joint events C_1C_2, C_1E_2, E_1C_2, and E_1E_2 (see Table 20.6). If, instead of a simple α for all subject items, there was a different α_i for all subject items, then the expected results for the four joint probabilities would be as indicated for the incremental model with individual differences in Table 20.6. The assumption of different learning rates for each subject item requires that the second and third joint events be identical, an assumption contrary to the observed results. Thus, individual differences in learning rate will not explain the results. If a retention factor assumed to vary across subject items is included, the four probabilities listed in the next-to-last column of Table 20.6 result. The parameter β_i is the probability of remembering the ith subject item from T_1 to T_2. Here, as the data require, there is a difference between the second and third probabilities. But can the parameters be estimated to make a good fit? The problem is clear: Either a small α or a small $\Sigma(1-\beta_i)/N$ is needed to make E_1C_2 near the zero observed. However, if α is small, then C_1C_2 cannot be adequately fit, and if $\Sigma(1-\beta_i)/N$ is small, C_1E_2 cannot be adequately described.

Estes goes on to consider the possibility that there is some learning on test trials. Assume α is the probability of a correct response after R. Assume that the incremental linear operator

$$P(T_2) = (1-\beta)P(T_1) + \beta$$

is applied when the correct response is made on T_1 and the decremental operator

$$P(T_2) = (1-\beta)P(T_1)$$

is applied when an error occurs on T_1. The idea here is that the only reasonable response to learn on test trial T_1 is the response made, for no feedback informs the subject about the correct response. The theoretical results in the last column of Table 20.6 again show that C_1E_2 and E_1C_2 should be equal. Thus, reasonably simple assumptions do not bring an incremental model into agreement with the data.

As was mentioned above, the prediction of $\alpha, 0, 0, 1 - \alpha$ for the four probabilities does not do very well either. However, a simple suggestion that forgetting occurs between T_1 and T_2 does account for the data quite well. The prediction is then $\alpha\beta$, $\alpha(1 - \beta)$, 0, $1 - \alpha$ with probabilities .241, .151, .000, and .608. (See Column 4 of Table 20.6.) The only flaw seems to be the .017 value for E_1C_2, and if there was any small probability of correct guessing this discrepancy could easily be accounted for. Estes' work thus implies that learning is all-or-none but that forgetting occurs.

Before discussing further the explanations for the forgetting factor, we should note the arguments against the position Estes takes and alternative theoretical approaches. The strongest attack came from Underwood and Keppel (1962) who criticized the results of the R T_1T_2 experiment on both theoretical and empirical grounds. Their theoretical argument was essentially that an incremental model of the Hullian type could account for his results. (Note that the incremental model discussed above is not a Hullian model but one related to statistical learning theory.) Underwood and Keppel make the point that the very concept of a threshold implies that items well below it will be wrong twice in a row and items well above the threshold will be correct twice in a row. Items which are correct and then wrong, or vice versa, can be accounted for by assuming they are close to the threshold and then invoking the oscillation principle. However, there seems to be a flaw in this line of reasoning. If oscillation is introduced, then a probability of being above threshold is associated with every item. The analysis made above holds exactly as Estes developed it. The only solution is to assume that the oscillation value or inhibition is not truly random but is correlated from trial to trial, an assumption that is possible but that is extremely unparsimonious and mathematically intractable. The second point made by Underwood and Keppel is that items are not learned at the same rate. In the context of the Hullian model, this would mean that some items may be above threshold while others are not. Assume that a proportion β are below threshold. These will give two errors in succession on the T_1 and T_2 test trials. The $1 - \beta$ remaining items will be above threshold and the subject will have some probability θ of being correct. Thus, two correct responses will have probability $(1 - \beta)\theta^2$; a correct and an error response, in either order, will have probability $(1 - \beta)\theta(1 - \theta)$; and two error responses will have probability $\beta + (1 - \beta)(1 - \theta)^2$. Thus, a higher proportion of pairs of errors, E_1E_2, are allowed by this assumption, but the E_1C_2 and C_1E_2 outcomes still have the same probability. Again individual differences in θ will not help. However, these arguments are against only one interpretation of Hullian theory and other interpretations could be made. In fact Restle (1965) has illustrated how a number of different incremental models could still lead to all-or-none learning.

Underwood and Keppel's empirical arguments against Estes' experimental procedure are much harder to evaluate. However, in light of all the research related to the all-or-none issue, the particular arguments against one experiment should not be overweighted.

Other extensions of the RT_1T_2 design have been made. For example, Estes, Hopkins, and Crothers (1960) discussed the effect of inserting multiple reinforcements between test trials. The experiment raised a number of questions about the simple design. For example, do multiple reinforcements increase retention? Estes et al. concluded that they did not, but they found that multiple test trials followed by reinforcements did increase retention. There was a sign of increased stereotypy in responding over repeated test trials, seemingly implying a learn-

ing process on the test trial—but learning of the response made rather than of the correct response. They also observed a retention loss between T_1 and T_2. Their explanation of the retention loss was that the stimulus conditions on the second test trial were different from those on the first test trial, and this produced a decrement in performance. It could also account for the observed better retention with test trials interspersed between reinforced trials as opposed to reinforced trials alone, that is, $RTRT_1T_2$ shows better retention than RRT_1T_2. In the mixed test and reinforced trials condition, there is more change in the stimulus from one reinforcement to another. This would presumably produce better retention. Izawa (1966, 1967) has followed up this last idea in a series of experiments. She applies the stimulus fluctuation model of stimulus sampling theory with a great deal of success (see p. 929). Although other researchers such as Seidel (1963) and Jones (1962) have raised questions about the miniature procedure and the interpretation given to the results, the weight of the evidence seems to favor an all-or-none learning process with a forgetting process due to stimulus change. Other factors are no doubt involved in many experiments, but their effects are small in comparison to all-or-none learning and forgetting over repeated test trials.

The all-or-none model for the traditional PAL procedure Bower (1961) introduced the one-element Markov chain model to describe paired-associate learning. (Although Estes [1959a], and Suppes and Atkinson [1960] had used a one-element model for analysis of probability-learning experiments, it was inadequate for that experimental routine.) The simplicity of the one-element model made it very tractable and Bower derived many statistics for the learning process. Some of these will be derived here. Much of the material is similar to that derived for the concept-identification model and the reader may wish to refer back to it for a review (see page 950).

Axioms: The main assumptions can easily be stated.

(1) *Each item is to be represented by a single stimulus element which is sampled whenever the stimulus item is presented.*

(2) *The element is in one of two conditioning states; C_0 or C_1, where C_0 means that the element is not conditioned and C_1 means that it is conditioned.*

(3) *On each trial when the item is reinforced, the element changes states according to the following transition matrix* **T**, *where c is the probability of a transition from state C_0 to state C_1 on each reinforced trial.*

$$\mathbf{T} = \begin{array}{c} \\ C_1 \\ C_0 \end{array} \begin{array}{cc} C_1 & C_0 \\ \hline 1 & 0 \\ c & 1-c \end{array} \quad \begin{array}{c} P\ (correct) \\ 1.0 \\ g \end{array} \tag{55}$$

(4) *The parameter c is assumed to be a constant for each and every trial.*

(5) *In state C_1, the probability of a correct response is 1.0 and in state C_0 the probability of a correct response is g.*

Usually, g will be $1/r$, where there are r responses from which the subject may choose. Of central interest in the mathematical development are the probabilities of being in the two states on any trial. Let $p_{i,n}$ be the probability of being in state C_i on trial n. Then, $\mathbf{P}_n = (p_{1,n}, p_{0,n})$ is the vector of state probabilities on trial n. Because, at the beginning of the experiment, the subject does not know the correct response for a stimulus item, it is natural to assume that all subject items start in state C_0 on trial 1, that is, $p_{0,1} = 1$.

Notice that this is a model for the acquisition of a single item in a list of paired-associate items. Any interaction between the learning of various items is avoided. The theory thus directly denies the principle of stimulus interaction and confusion, which was emphasized by Gibson (1940). The rationale for this seemingly unreasonable assumption lies in the rules of application for the theory. (It is not claimed that this model is appropriate for all paired-associate learning

situations; in particular, it is probably not appropriate for lists composed of pairs of nonsense syllables.) The axioms state that the stimulus may be represented by a single element. The model also assumes that the subject knows the responses which are to be associated to the stimuli since when he does not know he is to guess.

Learning curve. To derive the learning curve, we must know the probability of being in states C_0 and C_1 on each trial. It is clear from the transition matrix that there is no transition from C_1 to C_0. Thus, because $p_{1,n} + p_{0,n} = 1$, $p_{1,n} = 1 - p_{0,n}$. If we can derive $p_{0,n}$, then both the state probabilities will be known. The value $p_{0,n+1} = p_{0,n}(1 - c)$ is the recursion relating the state probabilities and has a solution

$$p_{0,n} = (1 - c)^{n-1} \tag{56}$$

Note that, in general, all state probabilities can be solved by direct matrix equations. Of course, a matrix solution would be required only when the above simple calculations did not work. In general,

$$\mathbf{P}_{n+1} = \mathbf{P}_n\mathbf{T}$$

which has the solution

$$\mathbf{P}_n = \mathbf{P}_1\mathbf{T}^{n-1} \tag{57}$$

Of course, in this equation we must find the powers of **T.** For the transition matrix above (Equation 55)

$$\mathbf{T}^{n-1} = \begin{array}{c|cc} & C_1 & C_0 \\ \hline C_1 & 1 & 0 \\ C_0 & 1 - (1 - c)^{n-1} & (1 - c)^{n-1} \end{array} \tag{58}$$

For the learning curve in this case we shall derive the proportion of errors on each trial. Because the probability of an error is $1 - g$ when the element is in state C_0, and zero in state C_1, the

$$P\text{ (error on trial } n) = q_n = p_{0,n}(1 - g) = (1 - g)(1 - c)^{n-1} \tag{59}$$

This is a geometric distribution function and does not differ from the learning curve predicted by the application of simple linear operators (Equation 59 is 1 minus Equation 5 with c replacing θ and g replacing p_1).

The distribution of the total number of errors. Let T be the statistic representing the total number of errors that a subject makes on a particular item before the item is learned. (For all statistics to be derived, we assume that all items are repeatedly presented until learned, that is, until they are absorbed into the absorbing state C_1.) First, what is the probability of no errors? Because we assume that each subject-item starts in state C_0 on trial 1, the subject must guess correctly until the item is conditioned. We write a sequence with zero for correct and 1 for error and indicate the terminal string of zeros generated in state C_1 by a –. Thus, $T = 0$ for all of the following sequences: 0–, 00–, 000–, 0000–, . . . with probabilities gc, $g(1 - c)gc$, $g^2(1 - c)^2gc$, $g^3(1 - c)^3gc, \ldots$, respectively. The 0– string occurs if the subject guesses on the first trial and then moves to state C_1 (gc) with probability c. The 00– sequence occurs if the subject guesses on trial 1 (g), does not condition $(1 - c)$, guesses correctly again (g), and conditions on trial 2 (c), yielding the $g(1 - c)gc$ probability. In each case the subject guesses correctly as long as he does not condition, then guesses correctly and conditions. In general we have the probability $g^j(1 - c)^jgc$ for the sequence with j correct responses before conditioning. We wish to sum these probabilities for all $j = 0, 1, 2, \ldots$ to get the $P(T = 0)$:

$$gc \sum_{j=0}^{\infty} [g(1 - c)]^j = \frac{gc}{1 - g(1 - c)} = gb \tag{60}$$

where b represents the probability that no more errors will be made after the response in state C_0. Now, the following argument yields $P(T = 1)$. If b is the probability that no further errors will be made after an error (or after a correct response in state C_0), then $1 - b$ is the probability that at least one further error will be made. First, there must be at least one error $(1 - gb)$; second, one error

TABLE 20.7 COMPARISON OF TWO METHODS OF COMPUTING THE STATIONARITY STATISTIC FOR THE HYPOTHESIS AND ONE-ELEMENT MODELS

		All-or-None Model	
		One-element	Hypothesis
Statistic	P (error on trial $n \mid n <$ trial of last error)	$1 - g$*	$\frac{(1-c)q}{(1-cq)}$†
	P (error on trial $n \mid n \leq$ trial of last error)	$1 - g + gc$	q

*$g = P$ (correct response) in the PAL model.
†$q = P$ (error response) in the CL model.

must occur $(1 - b)$; and third, no further errors can occur (b). The error response ensures that the subject is in state C_0, allowing us to use b for the probability that no further errors will be made after a response in state C_0. Thus, $P(T = 1) = (1 - gb)(1 - b)b$. For two errors, again $T \neq 0$, which has probability $1 - gb$; two errors must be made, which has probability $(1 - b)^2$, and no further errors can occur, which has probability b. So, $P(T = 2) = (1 - gb)(1 - b)^2 b$. In general,

$$P(T = k) = \begin{cases} gb & k = 0 \\ (1 - gb)b(1 - b)^k & k \geq 1 \end{cases} \quad (61)$$

The trial of the last error. Let L represent the trial of the last error and let $L = 0$ indicate no errors, which has probability gb. For $L = k$, we must have an error on trial k, then no more errors. To have an error on trial k, the item must be in state C_0 on trial k $((1- c)^{n-1})$; the subject must guess incorrectly $(1 - g)$; and no more errors can be made after the error response in C_0 (b). This leads to

$$P(T = k) = \begin{cases} gb & k = 0 \\ b(1 - g)(1 - c)^{k-1} & k \geq 1 \end{cases} \quad (62)$$

Bower derived many other statistics, including run probabilities for error and correct responses, autocorrelation of errors with lag m, distribution of the number of errors between the kth and $(k + 1)$st successes, and the distribution of the number of correct responses between the kth and $(k + 1)$st error. One statistic of interest, because it seems so counterintuitive, is the expected number of errors after the kth error. Let us first compute the expected number of errors for an item starting in state C_0 on trial 1, that is, the expected number of errors per item in the entire experiment. Using Equation 61,

$$E(T) = (1 - gb)b\sum_{k=1}^{\infty} k(1 - b)^k = \frac{1 - g}{c} \quad (63)$$

Now assume the kth error has been made; then with probability $(1 - c)$ the item does not condition on the error trial and remains in state C_0. However, starting in state C_0 was exactly the initial condition used to compute $E(T)$ in Equation 63. Thus, the process is a renewal process, and the expected number of errors after any error is $(1 - c)E(T)$, a constant. One further point should be made about this model. Like the all-or-none model used for concept identification discussed earlier, it predicts stationarity. Until the item enters the absorbing state C_1, the subject should be performing at a chance level. All the statistics used for the hypothesis model to test for stationarity can be applied here also. However, we must again emphasize the importance of careful calculations and derivations. In this model, the stationarity statistics should be computed only on the trials before the last error. That is, in the one-element model for PAL, the last error is not included, whereas in the hypothesis model for CL, the last error should be included.[10] Table 20.7 indicates the basic results. Thus, although a constant probability is expected regardless of how the statistic is computed, the value will not be the guessing rate $(1 - g)$ in PAL or q in CL unless the last error is excluded in the computations for PAL and included for CL.

[10] For the interested reader, these stationarity curves are worked out by Batchelder, Bjork, and Yellott (1966).

Evaluation of the One-element model Early applications of the one-element model were exceptionally successful (Bower, 1961). However, these studies made severe restrictions on the stimuli and the responses. In particular, most of them were studies involving two responses or verbal discrimination. Restle (1965) noted a fact about such studies which has been obvious to many researchers. With only two responses, the subject might use a strategy of list learning, attending to items associated with one of the responses and ignoring items associated with the other response. When an item is presented, the subject simply asks if it is included in the list of items he is using. If it is, the response is known; if not, the item requires the other response. Although most of the studies successfully described by the one-element model probably did not involve learning of this type, some may have. In any case, the success of the all-or-none model was soon to be questioned.[11]

Multistage Models for PAL

At the beginning of our discussion of PAL, we noted that there were three components to the learning: response learning, association, and stimulus discrimination. Can the failures of the one-element model be attributed to one of these? Actually, all three have been suggested, and in the following pages we shall discuss some of the suggested revisions.

Response factors Mandler (1954) discussed the need for segmented response units to be integrated into a whole response before they could become connected to the stimulus in the situation. Underwood, Runquist, and Schulz (1959) showed experimentally that variables that retard response integration would also affect PAL in a way consonant with the theory that the responses had to be learned before the stimulus-response association occurred. Using PAL lists which varied in the meaningfulness of the responses, they assumed that highly similar responses would be learned more easily, and thus the total PAL problem would be easier since the responses would not have to be learned. Furthermore, if the responses were known, then the lists should not differ significantly. The results of their experiments tended to confirm the hypothesis that response learning is one of the component processes in PAL learning.

One explanation for some of the failure to find all-or-none learning can be made in terms of response-learning factors. In the successful applications of the all-or-none model, the number of response classes has usually been small (normally two), and subjects simply have not had to learn responses. This has not been the case for PAL experiments in general, which have, in fact, involved response learning. Crothers (1964) attempted to show directly that the one-element model would not work with response learning. He used the RTT design with some variations and a response set consisting of the six responses: red circle, red square, green circle, green square, blue circle, and blue square. The subject could guess the color (red, green, or blue) and he could guess the shape (circle or square). However, in order to learn which response went with which three-letter trigram stimulus, two responses had to be hooked up. Crothers assumed that each response would be independently hooked up in an all-or-none fashion. The same learning rate was not assumed for each response component. We see here that the final learning will not be all-or-none but rather will involve a two-stage process. However, the underlying processes are assumed to be all-or-none. The fit of the model was only moderately successful. The assumption of independent learning of the two-response components was perhaps the weakest assumption.

[11] It is scarcely surprising that so simple a theory was questioned, particularly when the exactness of its various predictions is considered. By a simple increase in the number of subjects, any slight deviation from the theory could be made significant. In fact, in terms of scientific strategy, the ability to test theories with extremely powerful statistical tests has raised some serious second thoughts about the adequacy of simple goodness-of-fit tests. The strategy now suggested as more appropriate is that of choosing the better of a number of theories rather than trying to establish that the theory cannot describe the data. (For a detailed statistical treatment of this question, see Kraemer, 1965.)

We mentioned earlier that the all-or-none model was most successful when only two responses were involved. One explanation for the failure of the model with more than two responses is that subjects eliminate the learned responses and guess more efficiently. Thus, given eight stimulus items and eight response items, when three of the stimulus-response pairs have been learned, the subjects may begin guessing on unlearned items from the set of responses they have not yet used. This would change the guessing rate and distort the fit of the model. A related explanation is that, for each item, the subject learns not only the correct response, but also learns which responses are not correct. With the correction procedure this assumption is not too reasonable since the correct answer is seen on every trial and it is rehearsed instead of the error response. But with the noncorrection procedure, the assumption becomes plausible. For example, assume that there are r responses in a noncorrection procedure. When a subject makes a wrong response, he is not told the correct answer but is told simply that he is wrong. A rational strategy for the subject would be to learn which responses are wrong; then, the next time the item is presented, he could choose his response from the remaining possible responses. Millward (1964a) developed a Markov-chain model for such a learning process. A related model was introduced by Nahinsky (1964, 1967).

Bower (1962) considered the general relationship between the correction and noncorrection routine. In the latter routine, when a subject makes a wrong response, the experimenter simply says "wrong." If there are only two responses, the obvious assumption is that the other response is correct. However, if multiple responses are involved, the subject must act in some other, more complicated way. In a preliminary experiment, Bower found that nothing was learned during error trials in two groups given three and eight response alternatives. His explanation was that the subjects responded emotionally to being told that they were wrong and thus did not act rationally. He then considered a more general routine that allowed for a partial correction along with correction and noncorrection. In partial correction, the subject is not told that he is wrong; instead he is given a subset of the alternative responses which includes the correct response. Given instructions about the procedure, the subjects might not be so likely to act emotionally and more rational behavior might result. Bower assumed that the subjects would select an item from the subset and rehearse it. If the selected item was correct, then it was learned. If it was wrong, then, on the next trial, the subjects would again choose from the presented subset. After the first correct response was made for a given item, the item would either be learned or it would not be learned. If it was not learned, Bower assumed that the subjects would recognize the correct response in the subset and would select it. Thus, after the first correct response, all trials for an item would be essentially correction trials. Bower ran an experiment to test these ideas using three- or eight-response alternatives and a subset of size 2. Correction, noncorrection, and partial correction groups were run. The learning parameter c of the one-element model was estimated from the correction group and was "dragged" to the partial and noncorrection groups. The theory was modified according to the set of assumptions made above for these groups. The modified theory involved only the parameter c. The all-or-none theory described the data very satisfactorily.

The discussion just presented illustrates how various aspects of the PAL procedure related to the response phase of learning can be analyzed and integrated with the all-or-none model of learning. In the general PAL experiment with paired associates using nonsense syllables for responses, the subject would presumably have to learn each of the nonsense syllables—and learn to differentiate them also—before he could respond correctly. Further work on the integration of models for response learning and association learning is needed. The fact that all PAL experiments do not show all-or-none learning

is not conclusive evidence against this hypothesis unless we can be sure that the response-learning phase is not contributing to the process. This is the main point made by the all-or-none theorists at this time.

Association processes If the response-learning process is effectively eliminated, will the basic association process of learning always be all-or-none? If not, what might it be? Earlier in this section we reviewed the Hullian theory involving habit strength, threshold, and oscillation and saw that it proposed a complicated process of the incremental type, similar in some respects to the linear operator model. Between the linear processes and the all-or-none processes, there are multiple-step processes. We now review three classes of multiple-step models: the *N-element model,* the *random-trial-increments (RTI) model,* and the *short-term memory (STM) model.*

Consider first the N-element pattern model (Estes, 1959a; Atkinson & Estes, 1963). The N-element model is a natural generalization of the one-element model.[12] On each trial, one of the N elements is randomly sampled. Each element is either conditioned to the correct response or it is not conditioned. Generally, if it is not conditioned, the subject is assumed to guess. The reinforcement conditions the sampled element to the correct response with a probability c; fails to condition the sampled element with a probability $1 - c$. After the reinforcement, the element is returned to the pool of elements. The states of the process are simply the number of elements conditioned to the correct response. Thus there are $N + 1$ states representing the number of elements conditioned, $0, 1, \ldots, N$. A transition from state i to state $i + 1$ occurs with probability $c(N - i)/N$, for with probability $(N - i)/N$ an unconditioned element is sampled, and with probability c the sampled element is conditioned. If the process is in state i, then the probability of a correct response is $1(i/N)$ when a conditioned element is sampled, and $(1 - i/N)g$ when an unconditioned element is sampled, or, on the average, $i/N + (1 - i/N)g$, where g is the probability of guessing correctly when an unconditioned element is sampled. The subject starts with a probability g of a correct response and moves by steps of $(1 - g)i/N$, $i = 1,2,3 \ldots N$ until perfect learning has occurred. Of course the increments do not occur on every trial, but depend upon the state i and the learning parameter c. Let us consider the case where $N = 2$ and derive the learning curve for the process.

The states are defined by the number of elements conditioned, that is, S_0, S_1, and S_2 for 0, 1, and 2 conditioned elements, respectively. The transitions between states define the transition matrix of the Markov chain, **T**.

$$\mathbf{T} = \begin{array}{c} S_2 \\ S_1 \\ S_0 \end{array} \begin{array}{|ccc} S_2 & S_1 & S_0 \\ \hline 1 & 0 & 0 \\ \frac{c}{2} & 1 - \frac{c}{2} & 0 \\ 0 & c & 1 - c \end{array} \quad \begin{array}{c} P(\text{correct}) \\ 1 \\ \frac{1}{2} + \frac{1}{2}g \\ g \end{array} \qquad (64)$$

Because there is no transition from state S_1 to S_0, the state probabilities are fairly easy to compute (see p. 991). (The computation is instructive because it introduces a new mathematical concept, the convolution of two sequences; see Feller, 1957, p. 250.) First, the probability of remaining in state S_0 is $1 - c$. The recursion is exactly the same as that presented in Equation 56; $P(S_{0,n}) = (1 - c)^{n-1}$. We have assumed that the process starts in state S_0, so $P(S_{1,1}) = 0$. A step-by-step calculation of the probability of being in state S_1 on successive trials will lead to the probability of being in state S_1 on trial n, $P(S_{1,n})$. The basic recursion is easily stated: $P(S_{1,n+1}) = (1 - \frac{1}{2}c)P(S_{1,n}) + cP(S_{0,n})$. Hence,

$$\begin{aligned} P(S_{1,2}) &= (1 - \tfrac{1}{2}c) \cdot 0 + c \cdot 1 = c \\ P(S_{1,3}) &= (1 - \tfrac{1}{2}c) \cdot c + c(1 - c) \\ P(S_{1,4}) &= (1 - \tfrac{1}{2}c)^2 \cdot c + (1 - \tfrac{1}{2}c)(1 - c)c \\ &\quad + (1 - c)^2 c \end{aligned}$$

[12] Historically, the N-element model is derived from statistical learning theory (see p. 936 and Estes, 1959a).
Figure 20.14. Examples of individual learning curves for six models. The models differ in the manner in which the probability of an error response decreases toward zero.

To derive the three terms of $P(S_{1,4})$, first, a transition is made immediately to state S_1 on trial 1 with probability c, and the process remains in state S_2 for two trials with probability $(1 - \frac{1}{2}c)^2$. The second term occurs when the process stays in state S_0 for one trial, then moves to state S_1 and remains there for one trial. Finally, the last term occurs when the conditioning of the sampled element does not occur for two trials and then the element sampled on the third trial is conditioned. The pattern should be clear:

$$P(S_{1,k}) = c[(1 - \tfrac{1}{2}c)^{k-2} + (1 - \tfrac{1}{2}c)^{k-3}(1 - c) + (1 - \tfrac{1}{2}c)^{k-4}(1 - c)^2 + \cdots + (1 - \tfrac{1}{2}c)(1 - c)^{k-3} + (1 - c)^{k-2}] \quad (65)$$

A convolution is defined as a sequence c_k, $k = 1, 2, \ldots$, which results from the sum of the products of two other sequences: let a_i and b_j be the two sequences; then $c_k = \sum_{i=0}^{k} a_i b_{k-i}$. If we think of the two sequences as $(1 - \frac{1}{2}c)^i$ and $(1 - c)^j$, the terms in the bracket in Equation 65 form the kth term of the convolution for $k > 2$. The first and second terms of the convolution are $P(S_{1,1}) = 0$ and $P(S_{1,2}) = c$. Equation 65 can be written more concisely:

$$P(S_{1,k}) = c\sum_{i=0}^{k-2} (1 - \tfrac{1}{2}c)^i(1 - c)^{k-2-i}$$

$$= c(1 - c)^{k-2} \sum_{i=0}^{k-2} \left(\frac{(1 - \frac{1}{2}c)}{(1 - c)}\right)^i \quad (66)$$

Equation 66 is a sum of a geometric series with the solution

$$P(S_{1,k}) = 2[(1 - \tfrac{1}{2}c)^{k-1} - (1 - c)^{k-1}] \quad (67)$$

The learning curve is then simply

$$P(\text{error on trial } k) = P(S_{0,k})(1 - g) + P(S_{1,k})\tfrac{1}{2}(1 - g) = (1 - \tfrac{1}{2}c)^{k-1}(1 - g) \quad (68)$$

The idea of two states is important, and various models similar to the one sketchily presented here have been developed for a number of learning situations (Kintsch, 1963; Suppes & Ginsberg, 1963; Bower & Theios, 1964; Theios & Brelsford, 1966).

The linear model and the one-element model represent two extremes, which are illustrated in Figure 20.14 where the change in response probability for an individual subject is plotted. For the linear model, Figure

20.14D, all subjects would be identical to the curve presented. For the one-element model, the subjects would make the jump to zero probability on different trials, depending on the statistic for the trial of the last error. The curve for the one-element model (Figure 20.14A) shows a subject who responds at chance on trials 1,2,3, and 4 but who becomes conditioned to make the correct response on trial 4 so that he is correct on trial 5 and all later trials. Figure 20.14B illustrates the effects on the learning process produced by assuming more than one element; it presents the curve of an individual subject as interpreted by the two-element model. Figure 20.14E presents the curve of an individual subject as interpreted by the four-element model. Note that, in a multiple-element model, each subject passes through the same states but not necessarily on the same trials. Figure 20.14C represents graphically the assumptions of the random-trial-increments (RTI) model, which combines the linear model and the one-element model. Let q_n be the probability of an error on trial n. Let c be the probability that a reinforcement is effective on any trial. Then, the model can be stated as

$$\begin{aligned} q_{n+1} &= \alpha q_n \quad \text{with probability } c \qquad (69) \\ q_{n+1} &= q_n \quad \text{with probability } 1 - c \end{aligned}$$

The first equation is simply the linear-operator model. But the RTI model, unlike the linear-operator model, does not allow a change on every trial. The effective trials are determined by a random Bernoulli process with probability c. Figure 20.14C shows one possible sequence which follows an RTI model. In the example, $\alpha = 3/4$ and $c = 1/2$. The subject starts at chance (1/2) on trial 1, on which reinforcement is effective, and the new probability of an error is $\alpha q_1 = 3/8$. He stays at 3/8 on trials 2 and 3. On trial 3, reinforcement is again effective, yielding the new probability $\alpha^2 q_1 = 9/32$ for trial 4. Trial 4 is also effectively reinforced and the subject's error-response probability changes to $\alpha^3 q_1 = 27/128$ for trial 5. This learning curve for an individual subject illustrates two crucial points about the RTI model. First, unlike the case with the linear model, every trial is not effectively reinforced. Second, the response probability changes in accordance with the linear-operator model, $q_{n+1} = \alpha q_n$. In other words, this model assumes that an effective reinforcement changes the subject's response probability in accordance with a negatively accelerated growth function. By setting the parameters c or α to a particular value, either the linear model or the one-element model results. To illustrate, let $c = 1$. Then, every trial is effectively reinforced and the linear model results: $q_{n+1} = \alpha^{n-1} q_1$. However, by setting $\alpha = 0$, the one-element model results. One advantageous feature of the RTI model is that, when it is applied, the estimated values of the parameters will determine whether a pure linear model or a pure all-or-none model best describes the data. If $c \neq 1$ or $\alpha \neq 0$, then neither model is satisfactory. For a number of experiments, Norman (1964) and Atkinson and Crothers (1964) found the RTI model to be better than either the one-element or the linear model. Of course, any deviation in the data from the predictions of either of these "extreme" models means that the RTI model has to be superior, so the results of their experiments imply that neither extreme model is generally adequate.

A third way of relaxing the all-or-none process is to introduce a short-term memory factor. Broadbent (1958), Peterson and Peterson (1959), Murdock (1961), Melton (1963), and others have investigated the role of STM. As we saw earlier, subjects in probability-learning experiments remember the five or so most recent events, and in concept-learning experiments, subjects remember the previous hypotheses tested as well as specific stimuli presented on past trials. Similarly, in PAL and SL, subjects remember almost perfectly the last few items presented. This facet of memory has not yet been incorporated in any way in the conditioning models discussed above, but there are some historical precedents for introducing memory processes. Pavlov introduced the notion of a stimulus trace to ac-

count for trace conditioning. Hull used the same notion to bring together in time the stimulus, response, and reinforcement, which usually were separated temporally. A more recent and dynamic view of the "trace" of a stimulus was introduced by Broadbent (1958).

The main point of interest to us here is the postulation of two types of memory, short-term memory (STM) and long-term memory (LTM). Long-term memory may be defined as the ability to recite a list, respond to a stimulus, remember an association, and so on, following some long interval of time after the material was practiced or presented. It is obviously very much related to what is meant by learning itself. Short-term memory, in contrast, is the appropriate performance immediately or very shortly after the material was presented. It is usually conceived of as different from LTM because it has different characteristics, such as a rapid rate of decay, and a limit to the amount of material which can be remembered. Since any performance measure of STM usually mixes both of these two memory types, it is not easy to prove that the two types of memory exist. The arguments for a single type of memory derive mostly from the experiments demonstrating similar processes in STM and LTM experiments (Hebb, 1961; Melton, 1963; Postman, 1964). Arguments for two types of memory stem from experiments that show rapid forgetting due to interruption of rehearsal (Broadbent, 1958, 1963; Peterson & Peterson, 1959; Murdock, 1961). However, simply positing two types of memory does not help a great deal; in fact, it requires giving detailed specifications for two systems instead of one. The evidence supporting two types of memory, though not conclusive, seems sufficiently compelling to justify the development of theories assuming a STM process. A brief description of the STM process will help to explain the models to be presented.

Items in STM appear to become less available, either as a function of time or as a function of other items having been placed into the short-term memory. The difficulty of determining which variable—time or interference of new items—causes the loss of memory for items in STM arises because, if no items are presented during the time interval of interest, a subject can rehearse the items in the short-term memory. Hence memory for the items does not decay. If other items are presented, preventing rehearsal, memory loss can be due to either interference or decay (Melton, 1963; Wickelgren & Norman, 1966). If one assumes a STM, one generally (though not invariably) assumes that there are a fixed number of "slots" that hold encoded items. After each item is encoded, it is placed in a slot. Support for this idea comes from experiments showing that a single word and a single letter are forgotten at the same rate and also that three words and a three-letter nonsense syllable are forgotten at the same rate, but at a rate faster than that for single words or letters (Melton, 1963). Thus, the number of letters comprising the unit is not important, but the number of encoded units is. Another assumption often incorporated into STM models is that there are about seven slots in all. This assumption is related to the ubiquitous role of the number 7 in many information-processing tasks (Miller, 1956). Finally, if we assume a STM system, then the manner in which items go from STM to long-term memory (LTM) must be specified. At this stage in studies on memory, few conclusive answers are available. Nonetheless, theories of PAL and SL must take into account some version of stimulus-trace theory. The assumption of simple single-link associations is inadequate if only because, immediately after a single stimulus-response presentation, a subject has a very high probability of knowing the response to the stimulus. In contrast, after a short time interval, or after a few additional items have been presented, the probability of perfect recall decreases a great deal.

Atkinson and Crothers (1964) have incorporated the idea of a short-term memory into an all-or-none model of learning which assumes that an item can be in one of four

states. The first is a state, U, in which items are not encoded well enough to be placed into STM, and even rehearsal will not affect learning for them. However, after an item has been encoded, it can be in either the STM state, S, or in the forgetting state, F, depending upon some forgetting factor. Learned items are in the learned state, L. The following transition matrix summarizes the transitions between the states of the model.

$$
\mathbf{T} = \begin{array}{c|cccc} & L & S & F & U \\ \hline L & 1 & 0 & 0 & 0 \\ S & a & (1-a)(1-f) & (1-a)f & 0 \\ F & a & (1-a)(1-f) & (1-a)f & 0 \\ U & ca & c(1-a)(1-f) & c(1-a)f & 1-c \end{array} \quad \begin{array}{c} P(\text{correct}) \\ \hline 1.0 \\ 1.0 \\ g \\ g \end{array} \tag{70}
$$

We see from this matrix that the probability of encoding an item is c. After an item has been encoded, it remains encoded. It is placed in the permanent learning state L with probability a. If it is encoded, then, depending on the forgetting parameter f, the subject either responds correctly or he makes a guess. Figure 20.14F shows the response probabilities for a sample subject. Notice the subject jumps between knowing the answer and guessing. This model does not predict stationarity. It was applied to the results of eight experiments and found to be better than six other models, including the linear model, the one-element model, the RTI model, and the two-element model. However, this STM model has three parameters, whereas the others have one or two parameters. When c is a priori set equal to 1, a two-parameter version of the above model results. The two-parameter version of the model is still better than all the other models tested.

To account for the effect of list length in PAL, Calfee and Atkinson (1965) made the parameter f a function of the number of items that intervened between two presentations of the same item. The choice of the parameter f was based on results that show STM to be more a function of intervening items than of time. Unfortunately, Calfee and Atkinson's experiment does not separate time for decay from the number of intervening items and thus time and number of items are confounded. They found that learning, that is, entering the long-term memory state, had a higher probability when the transition was from state S than it did when the transition was from state F. However, these results were contradicted by those of an experiment by Greeno (1964, 1967), which showed that if an item was presented twice in a row, it was not learned any faster than those presented only once. Yet an item recently presented certainly should be in the short-term memory. Items repeated twice, but *not* in succession, were learned more rapidly.
Figure 20.15. Schematic representation of Bernbach's short-term memory model. The four subprocesses are those associated with (1) the tests, (2) reinforcement, (3) learning, and (4) the intertrial interval.

Bernbach (1965) based his STM model for paired-associate learning on results obtained by Peterson and Peterson (1962), which showed that with repetition the forgetting curve for STM decreased less rapidly. Bernbach assumed that an item started in a guessing state, G on trial 1 (Figure 20.15). Then, if it was guessed correctly, the item went into a STM state C, in which the response was remembered but not learned. From state C, the item was either forgotten during the interval between trials, with probability δ, or else it was held in C with probability $(1-\delta)$. When an item was in C and was reinforced, it went into C' with probability θ. In C' it was permanently remembered. If an item in G was guessed incorrectly, one of two transitions could take place. Either the error response could be placed in STM (this was introduced to account for *proactive inhibition*), with probability β, or the correct response could be placed in STM with probability $1-\beta$. Presumably, the correct response was placed in STM when reinforcement was effective. If the error response was placed in STM, it was forgotten with probability δ, or remembered with probability $1-\delta$. The important point about this model is that some of the subprocesses which have been postulated for PAL are built into the general model. Bernbach has shown how several subprocesses can be isolated for recombination in a miniature experiment (Jones, 1962) of the form $R_1R_2T_1T_2T_3T_4$. One subprocess is the effect of a test trial, a second is the effect of a reinforcement, a third is the effect of the intertrial interval, and a fourth is the transition from the STM state to the learned state. By estimating parameters involved in the various subprocesses, we can obtain some indication of what happens at each stage of a PAL experiment. Note that we have here the idea of building a general model from associative subprocesses, each of which can be analyzed by special experimental procedures.

We have examined a number of attempts to relax the strong all-or-none learning process. The rationale for the STM model seems clear enough—there are two memory processes and both must be included in any model of learning. The rationale for the RTI model is that, although learning is incremental, an item does not always receive an effective reinforcement. This could be due to a number of psychological factors. One might be attention, that is, a subject might be rehearsing one item while the next item is being presented. The second item would, essentially, not be reinforced. Another factor might be STM. Unless an item is in STM it may not be effectively reinforced. It is in STM with a probability c and not in STM with a probability $1-c$.

An argument for an N-element model might be based on the assumption of more molecular events such as the number of neural connections required to establish a reliable S-R bond or the number of stimulus components that must be connected.

The adequacy of these multistage models and the inadequacies of both the one-element model and the linear model imply that many situations involve a number of subprocesses that can be described by assuming that a stimulus-response bond is in one of a few states. At present, the STM process seems to be a promising one for accounting for these various states. However, an idea such as proactive interference may also be required; that is, if a subject makes a wrong response, the wrong response may be remembered instead of the correct response (see Bernbach's model). These various models for the association process are certainly not exhaustive. However, presenting them should help to make clear that a large number of ideas are possible and premature fixation on any one model is uncalled for at this time.

Stimulus variables We turn now to what is perhaps the most important process increasing the complexity of PAL learning, namely *stimulus confusion*. Perhaps the most important fact relevant to a treatment of stimulus variables in learning is the distinction between the physical stimulus as pre-

sented and the functional stimulus used by the subject. Lawrence (1963) referred to this functional stimulus as the "stimulus-as-coded" or "sac." Thus, a subject does not respond to a nonsense syllable TUZ as if it were composed of wiggly lines, but as the letters T, U, and Z or the sound /təz/. The way in which he responds determines what aspects of the set of stimuli may be confused. When the stimuli are composed of a number of dimensions, the subject may attend to only a few dimensions, or only a few values on each dimension. This idea of selective attention makes it even more difficult to postulate a one-to-one relationship between the stimulus presented and the functional stimulus (see Shepard, 1963; Shepard & Chang, 1963).

Still another manner of responding can influence the nature of the active stimulus. This is the notion of a mediated response whereby the stimulus itself may produce some encoded form which then elicits another response. The elicited response serves to differentiate this stimulus from all others and thus produces a unique stimulus. Mediated responses or mnemonic devices have a long history in the work on memory. The memory aids of so-called "memory wizards" involve making some unique association with each name or face. To this association, often bizarre in some respects, they can easily associate further material. Similarly, if subjects in PAL and SL experiments are trained to use mnemonic schemes, they perform much better. However, if the items are presented rapidly, there may not be time enough to evoke a mediated response, and the learning may still be relatively slow.[13]

In our discussion of PL, we observed that SLT could not handle discrimination problems in which certain stimulus components were shared by the two discriminative stimuli. We noted that, by assuming adaptation of these common elements, Bush and Mosteller (1951) and Bourne and Restle (1959) were able to account for the perfect learning which usually occurs in such situations. The Hullian notion of inhibition for the randomly reinforced components shared by the two discriminative stimuli is essentially the same form of solution as adaptation of cues.

In the preceding paragraphs, we mentioned three mechanisms which can be used to explain the same phenomenon. Any theoretical treatment of learning which emphasizes encoding, selective attention, or some kind of mediated response must incorporate these mechanisms into a complete model that explains how the stimulus (or the sac) gets connected to the response. There are a variety of possible association schemes. Those approaches that assume a continuous change in the strength of associations and those approaches based on attentional responses to crucial cues in the stimulus have been applied primarily to discrimination learning in animals and children (Sutherland, 1959; Atkinson, 1961; Zeaman & House, 1963; Lovejoy, 1966). The models we shall discuss here assume discrete changes in stimulus-response connections and have been developed more for human-learning paradigms.

The one-element model assumes that each stimulus can be treated as a whole; that the stimulus as coded is unitary and will be associated in an all-or-none manner with the response. Some stimuli might be composed of three (or, if they are words, more than three) letters, and, if the subject can produce a single sac functional stimulus, all-or-none learning can occur. One obvious way to relax the one-element model and allow for nonunitary stimuli would be to go to a two-element or N-element model and assume that subjects will make a random sampling of the component cues. However, such an assumption might be too restrictive. For example, there is a great deal of evidence (Underwood, 1963) that, while forming an association in PAL

[13] There has been a great deal of theoretical discussion concerning stimulus encoding, attention, and mediational responding. Although certainly related to paired-associate and serial learning, these topics are too general for discussion in this chapter. They are discussed in Chapter 17 on discrimination learning. Note also Shepard, Hovland, & Jenkins, 1961; Underwood, 1963; Shepard, 1964; Blough & Millward, 1965; and Wickelgren, 1965, 1966.

experiments, subjects predominantly attend to the first letter of a nonsense syllable. The N-element solution also has the difficulty, mentioned earlier, that perfect learning would not result if there were any common stimulus cues. Thus, if TUZ-3 and TOX-5 are two items in a PAL experiment, and if TUZ and TOX are each considered to be unitary stimuli, they can be learned perfectly in an all-or-none fashion according to the one-element pattern model. However, if they are not learned in an all-or-none fashion, a simple change to the N-element model is inadequate since perfect discrimination between the items could not occur. (We are assuming here that the sac would include common cues.)

Estes (1959a), Estes and Hopkins (1961), and Atkinson and Estes (1963) developed the mixed model to handle situations in which cues overlapped but in which perfect performance eventually resulted. The assumptions of the one-element model are made (see p. 990), but a new axiom is introduced: Before an item is conditioned, the response a subject makes to it is determined by the components which that item has in common with other stimulus patterns which are conditioned. The stimulus description axiom (see Axiom 1, p. 990) is changed slightly as follows:

"The effective stimulus S on any trial is partitioned into subsets $s_i (i = 1,2, \ldots r)$, where r is the number of response alternatives, and the ith subset contains the elements conditioned to response A_i." This new axiom permits each stimulus to be composed of subsets of elements conditioned to different responses. But how do component cues get conditioned to responses other than the correct response to the item? The basic assumption of the one-element model is that when the stimulus S is conditioned to the correct response, the subject always responds to the pattern as a whole. The components remain conditioned as they were before conditioning of the pattern. The mixed model does not modify this basic assumption. However, according to the mixed model, before this pattern-conditioning occurs, the various subsets can be conditioned to other responses. If the subset s_i occurs in both stimulus S_1 and S_2, and if S_2 is conditioned as a pattern to response R_1, then s_i in S_1 is conditioned to response R_1 also. If s_i also occurs in S_3, which is also conditioned before S_1, then S_2 or S_3, whichever occurred last, determines to which response s_i is conditioned. Not all subsets of each stimulus are necessarily conditioned. When a component is not conditioned, its contribution to the overall response probability is $1/r$ or a chance probability.

The response rule can now be stated. Assume that stimulus S is not conditioned as a pattern and that there are i cues conditioned to A_i, j cues conditioned to A_j, $j \neq i$, and k cues not conditioned, then

$$P(A_i) = \frac{i + (k/r)}{i + j + k} \tag{71}$$

$P(A_i|\text{S conditioned to } A_j \text{ as a pattern}) = 0$

$P(A_i|\text{S conditioned to } A_i \text{ as a pattern}) = 1.0$

The one-element model developed earlier is consonant with this formula if we assume that there are no overlapping cues. In such a case, conditioning S_j will not condition any of the subsets of S_i, and all subsets of S_i will remain unconditioned. Then, responding is $P(A_i) = 1/r$, where there are r responses.

Let us consider an example introduced by Atkinson and Estes (1963), paralleling closely the two-element model developed earlier. However, in this case, the two elements of each stimulus are not unique to each stimulus. The two stimuli can be represented by the elements a, b, and c: $S_1 = (a,b)$ and $S_2 = (a,c)$. We represent these as ab and ac. The responses are A_1 and A_2; that is, $ab - A_1$ and $ac - A_2$ represent the PAL list. The subsets consist of the individual letters, a, b, c. Before any reinforcements, all subsets are unconditioned. If S_1 is conditioned as a pattern and S_2 is not conditioned, then the components in S_2 are conditioned as follows: $a - A_1$, $c - A_0$; where the A_0 indicates un-

conditioned. Likewise, if S_2 is conditioned as a pattern and S_1 is not conditioned, $a - A_2$ and $b - A_0$. Finally, when both S_1 and S_2 are conditioned, each pair of components is treated as a single stimulus, $S_1 - A_1$ and $S_2 - A_2$. Hence the subject can be in one of four states of conditioning: (S_1,S_2), $(S_1, \overline{S}_2)$, $(\overline{S}_1,S_2)$, $(\overline{S}_1,\overline{S}_2)$, where the bar indicates an unconditioned stimulus pattern.

Let the vector of state probabilities on trial n be $\mathbf{P}_n = (p_{1,n}, p_{2,n}, p_{3,n}, p_{4,n})$ where $p_{i,n}$ is the probability of being in state i on trial n, $i = 1, 2, 3, 4$, corresponding to the list of states above. To see how response probabilities change, consider a PAL experiment in which there are reinforced trials followed by test trials, RTRTRT. . . . On each reinforced trial R both items are presented. The initial state probabilities are assumed to be (0,0,0,1), for there would be no way for the subject to know the correct response to either stimulus *ab* or stimulus *ac*. During the R trial, S_1, S_2, both, or neither of the stimulus patterns might be conditioned. Thus, for the first test trial, the state probabilities would be $[c^2, c(1 - c), (1 - c)c, (1 - c)^2]$. Now the average probability that an A_1 response would be made to the stimulus *ab* would be $[c^2 + c(1 - c)] \cdot 1 + \frac{1}{4}c(1 - c) + \frac{1}{2}(1 - c)^2$, where we have assumed a guessing probability of $\frac{1}{2}$. The probability that an A_2 response would be made to the stimulus *ac* would be the same. Note that a subject who learned S_2-A_2 and not S_1-A_1 would show a probability of responding to *ab* with A_1 of only $\frac{1}{4}$, less than his guessing probability of $\frac{1}{2}$. This reflects the negative transfer incorporated into the design. Yet perfect learning would eventually be accomplished.

The mixed model represents a first attempt to incorporate into an all-or-none model the effects of stimulus overlap. A number of experiments have been run to test the assumptions of the mixed model as well as variations in it. These experiments raise as many questions as they answer and for that reason they are worth reviewing at this time. Estes and Hopkins (1961) ran an experiment investigating the transfer during learning of stimuli with overlapping components. There were six stimuli and two responses. The PAL list consisted of Russian letters (designated here by *a, b, c,* and *d*) paired with a response that consisted of moving a lever switch up or down (designated here as 1 and 2). A cycle consisted of a single random presentation of *a*-1, *b*-2, *c*-1, *d*-2, and a double presentation of *ab*-1 and *cd*-2. After eight cycles and after 16 cycles of these stimuli, test trials were introduced. On the test trials, all single-, double-, and triple-letter combinations of *a, b, c,* and *d* were presented. The training items were repeated on the test trials to see if there was any decrease in performance during the test trials. Estes and Hopkins found that, although all six patterns were not completely correct, the subjects learned sufficiently well that further training could be expected to produce perfect learning. The double-letter stimuli were not learned more slowly than the single-letter stimuli. The subjects made more mistakes with components *b* and *c* than with components *a* and *d*, indicating transfer from the *ab* and *cd* patterns. A final result of some interest can be illustrated with the test pattern *abd*. The elements *a, b,* and *d* are the components of the stimulus pattern *abd*. The pair of letters, *ab*, in contrast, is referred to as a subpattern of *abd* because *ab* constituted a pattern in the original list. The letter pair *cb*, for example, was not a pattern in the original list and thus is not a subpattern here. The question of interest is whether a subject treats *abd* as a mixture of three simple components, *a, b,* and *d*, or whether a subject treats the stimulus pattern *abd* as composed of the subpattern *ab* and the component *d*. The former is referred to as the "molecular version" of the mixed model whereas the latter is called the "molar-mixed model." Estes and Hopkins found that early in learning, after eight cycles, the subjects seemed to use a mixture of both the molar and molecular models, but after 16 cycles they used the molar model for the most part. This finding complicates the mixed

model because transfer from conditioned patterns to components of unconditioned patterns might be in terms of components or subpatterns, and might even be a changing process with trials.

Another experiment by Friedman (1966) confirmed the result noted by Estes and Hopkins in which subjects demonstrated transfer from a pattern such as *ab* to a simple pattern such as *a*. He also found transfer from *a* to *ab*. However, the results became complicated when the transfer to novel compounds was considered. There were two groups defined by the response assignments. Group 1 had the list *a*–1, *b*–2, *ab*–3, and *ba*–3, and Group 2 had the list a–1, *b*–2, *ab*–2, and *ba*–2. These lists were expanded so that a total of 12 items occurred in which each of the three responses occurred equally frequently and all were associated with both single- and double-letter patterns. There was strong evidence that Group 2 subjects responded on the basis of subpatterns while Group 1 subjects did not. Friedman interprets the difference on the basis of the list itself. In Group 1, the components, *a* and *b*, were always assigned different responses than the double-letter patterns that contained them. In contrast, in Group 2, half of the components were consistent with the double-letter patterns. Thus, subpatterns produced by Group 2 were important; they appeared to be used by the subjects in the transfer tests. A further result of this study was that the frequency with which a given response was reinforced in the presence of a single cue did not determine response probability. This contradicted earlier work by Binder and Feldman (1960).

A more extensive test of the mixed model was made by Friedman and Gelfand (1964). They investigated seven transfer conditions, including double reinforcements, retroactive interference, proactive interference, retroactive facilitation, proactive facilitation and two control groups. The design was essentially a miniature experiment, R_1R_2T, in which various compound stimuli were reinforced on R_1 and R_2 and tested on T. For example, retroactive interference consisted of reinforcing *ab*-1 on R_1, reinforcing *ac*-2 on R_2, and testing *ab* on T. The proactive facilitation condition consisted of reinforcing *ac*–1 on R_1, *ab*–1 on R_2, and testing *ab* on T. They modified the mixed model presented earlier by assuming that a STM process was also involved. Thus, in the time from the reinforcement until the test, the pattern can be maintained in STM or lost. If it is maintained, the correct response is made. If lost, then patterns retained in STM with overlapping cues determine the response according to the mixed model. If no patterns with overlapping cues are in STM, then the subject guesses. All in all, the mixed model predicted the results fairly well. Two problems were noted: The proactive interference condition showed a greater loss than predicted and there was a greater number of intrusions in the retroactive interference condition than predicted.

A more elaborate experimental test of the mixed model was reported by Friedman, Trabasso, and Mosberg (1967), who were concerned with a question similar to that raised by Estes and Hopkins when they discussed the molar versus the molecular transfer of components. Here, Friedman et al. assume that a component can be conditioned to more than one response if it is part of more than one conditioned pattern. They also assume that the subject responds to an unconditioned stimulus by choosing only one component from the conditioned components. If no components are conditioned, the subject simply guesses. (This differs from the response rule of the earlier mixed model, which assumed weighted probabilities involving all components simultaneously.) Consider a stimulus with components a and *b*, both of which have been conditioned to one or more responses because both belong to one or more stimulus patterns which are conditioned. The important question is what determines which of the two conditioned components is chosen. One possible variable here is the overall frequency with which the component cue is presented, the assumption

being that frequency makes a cue salient. An earlier study by Binder and Feldman (1960) seems to support such a notion. A second possible variable is relevancy. A *relevant cue* is one that has consistently been paired with the same response; a *partially relevant cue* is one that is paired with more than one response but with unequal probabilities; an *irrelevant cue* is one which is paired with two or more responses with equal frequency. In the selection of a component cue for determining a response, the probability of selecting component *a* or *b* might depend upon the relevancy of the cues, that is, the more relevant cue would be more likely to be selected. In this experiment, Friedman et al. found that relevancy was important and frequency was not.

In an extensive series of studies on the same problem, Binder and Estes (1966) considered only cases of component transfer. Compound stimuli were composed only of components of previously reinforced patterns. Thus, the molar-mixed model is not of interest here. They found that the two main assumptions of the mixed model were supported. These assumptions are (1) the response rule of the mixed model, which assumes a weighted average of the components from other conditioned patterns, and (2) the matching rule, which assumes that if a component has been reinforced with probability π and $1 - \pi$ for two responses, the subject will respond to that component with probability π and $1 - \pi$. One new principle emerged from their work: It was the effects of novelty. Although the mixed model was fairly accurate, deviations that did occur were attributed to this so-called "novelty effect," which amounts to responding to a component that has occurred with less frequency in the set of stimuli. Because such low-frequency cues were often negatively correlated with relevancy, there was some indication that relevancy (or validity, as Binder and Estes call it) was the important variable. However, when relevancy was controlled, the results suggested that low frequency or novelty was the important factor. It is clear from these studies that further work is needed to untangle the critical variables controlling the subject's selection of components from stimulus compounds. The fact that novelty plays a role in the subject's responses to compound stimuli suggests that more than a simple learning process determines these responses. It may be that a number of different response strategies, as yet unspecified, determine much of the behavior.

Restle (1964) has developed a theoretical point of view compatible either with all-or-none learning or with learning involving a number of successive steps. However, according to Restle, the steps occur, not because the subject learns a number of molecular components, but rather because he uses a number of different learning strategies. Restle's theory often leads to specific models of a given situation, which are smiliar to those discussed above, but he derives his models from a different fundamental concept of the learning process. First, he assumes that every experience leaves a memory trace. This means that on every trial another trace enters memory (Restle, 1961). The learning problem for the subject is that of finding the relevant trace when it is needed. Traces are not assumed to decay. They become difficult to find because there are many of them to search and search rules fail. Relevant traces are retrieved from memory by "search strategies," which in PAL learning are mnemonic devices. In every learning situation a subject has a set of possible mnemonic devices. When a stimulus item is presented, the subject is assumed to select one of the possible mnemonic devices as an aid to remembering the item when it is next presented. Good mnemonic devices will allow retrieval of the correct answer; poor ones will not. Under some conditions, such as an experiment with practiced subjects who deliberately use mnemonic devices, learning may be all-or-none. Under other conditions, however, such as an experiment with highly confusing stimuli, more than one mnemonic de-

vice may have to be relied upon. For example, one mnemonic device may have to be selected to separate stimuli that are very similar and, in addition, another may have to be selected to connect the stimulus and the response together in some idiosyncratic way, simultaneously solving both the discrimination and the learning problems for a set of stimuli. Each item on the list may require a discrimination and an association mnemonic device.

Restle makes two specific assumptions about PAL learning which lead to his model for the PAL paradigm. The first is that the association process is an all-or-none process exactly like that of the one-element model discussed above. The constant probability of a correct response before the last error depends upon the assumption that strategies are either successful or unsuccessful, that there are no partially successful strategies. However, Restle does not believe that this assumption will always be true. The second assumption is that, in the association process, an unsuccessful strategy leads to a failure to recall. Such a failure requires the subject to guess and also to resample a mnemonic device. In contrast, if an unsuccessful strategy is selected in the discrimination process, one item will be confused with another item. Such confusion may not immediately lead to an error, and if it does not, resampling will not occur. However, eventually an error will be made, and the subject will select again from the pool of strategies. Thus, the discrimination process assumes the same model as the hypothesis-selection model discussed under the CL section, whereas the association process assumes the one-element model. These two processes are placed in succession and lead to a Markov chain with the following transition matrix. The parameter θ is the probability that a subject will select a successful association strategy, which takes the subject out of the guessing state S_0. The parameter d is the probability that the subject will select a successful discrimination strategy. The parameter p is the probability that he will make a correct response in the discrimination states S_1 and S_2. As long as the subject is correct, he will not select a new discrimination mnemonic. When he is wrong, with probability q, he will select another discrimination mnemonic and move to state S_3 where he will make no more errors. Note that if $d = 1$, the one-element model results, and if $\theta = 1$, then, after the subject has guessed on the first trial, the hypothesis-selection model results.

In a further development of these ideas, Restle (1964) has introduced another step to account for response generalization. In this same paper, Restle shows how the theory can be applied to analyze learning situations and to extract the different processes involved in the learning of a reasonably complex PAL experiment. In a later experiment by Polson, Restle, and Polson (1965), a list of 16 stimuli was presented in a standard unpaced anticipation PAL procedure. Eight of the stimuli were so constructed that four pairs of similar stimuli resulted. The other eight stimuli were very dissimilar. There were five responses, all of which were known to the subject. The purpose of the experiment was to show all-or-none learning for the unique stimuli and two-step learning for the confusing stimuli. The results support a two-process model for stimuli which require discrimination, but some discrepancies were found. In particular, it appears that the idea that each S-R association is made before the discrimination phase is not correct. For example, assume that the

$$\mathbf{T} = \begin{array}{c|cccc|c} & S_3 & S_2 & S_1 & S_0 & P(\text{correct}) \\ \hline S_3 & 1 & 0 & 0 & 0 & 1 \\ S_2 & d & q(1-d) & p(1-d) & 0 & 0 \\ S_1 & 0 & q & p & 0 & 1 \\ S_0 & \theta d & q\theta(1-d) & p\theta(1-d) & 1-\theta & g \end{array} \qquad (72)$$

two confusing pairs are *ab*-1 and *ac*-2. The model assumes that both *ab* and *ac* must be in either state S_1 or S_2 before confusions can occur. The subject only guesses at items in S_0. However, Polson et al. found that one of the pair of items could be in S_1 or S_2 while the other was in S_0. In the raw scores, one of the items of the pair of confusing items has a string of correct responses, while the other item shows confusion responses followed by a string of random errors.

Restle's approach is an attempt to integrate the theoretical positions of Gibson (1940), who emphasized the role of stimulus generalization and discrimination in PAL, and that of Underwood, Runquist, and Schulz (1959) and Underwood and Schulz (1960), all of whom emphasized response learning. A paper by McGuire (1961) also clearly pointed out the discrimination, association, and response learning factors and analyzed them from a Hullian point of view. Although McGuire's ideas (1961) are very similar to Restle's, the increased mathematical tractability of successive all-or-none processes over mixing habit strengths makes the Markov-chain model potentially more useful. It should be obvious by now that the strategy-selection theory, or variants of it, applies to both the CL experimental situation and the PAL situation.

Greeno and Scandura (1966) have used a verbal concept-learning situation to approach certain issues raised by the mixed model and the strategy-selection model. The mixed model assumes that the total pattern is associated to the correct response, but that transfer to similar stimuli is by components. Thus, any stimulus that contains components of a conditioned stimulus will show either a facilitative or an interference effect, depending on whether it has the same or a different response assignment. The strategy-selection model assumes that any subset of components of the stimulus may be used as the coded stimulus for conditioning. Transfer is limited to stimuli with the same encoded subset. The more general theory described by Greeno and Scandura (1966) allows for conditioning to any coded subset of components and transfer to any stimulus that contains components that are in the coded subset used in learning. Their analysis shows clearly the interweaving of ideas developed from stimulus-sampling theory and hypothesis-selection theory.

From our discussion of the past few pages, we can glean the major points of a complete theory of PAL. The theory allows for variation in the stimulus-encoding conditions, either by stimulus selection or mnemonics. It considers stimulus interaction factors at the level of the encoded stimulus. The association process is assumed to be all-or-none, either because basic conditioning is all-or-none or because strategy-selection is all-or-none. Short-term memory processes are incorporated when they are necessary. Response learning and differentiation are all taken into account. As yet the theory is somewhat vague in its statement of rules of correspondence; it is used mainly as an analytical device and its application depends to a great extent on the intuition of the experimenter. Although further work on the rules of correspondence is certainly needed, it may turn out to be impossible to state such rules in any single final form, for they no doubt will depend very heavily upon instruction, past learning, and developmental factors. To mention only one possible factor, consider the encoding of stimuli. For college students given the task of learning nonsense syllables, the first letter of the nonsense syllable is very salient. While this is a fact to be explored further, it is not necessarily the kind of information that should accompany a general theory of PAL. Each situation to which the theory is applied will no doubt require boundary conditions and specific rules for its application.

We conclude our discussion of PAL with the description of a theoretical approach that differs greatly in underlying concepts from the theories just described.

An Information-Processing Theory

The Elementary Perceiver and Memorizer (EPAM) was introduced and developed by Feigenbaum (1959, 1963), Feigenbaum and Simon (1961, 1962, 1963) and Simon and Feigenbaum (1964); it consists of two levels of analysis: a *microprocessing level* and a *macroprocessing level*. Hintzman (1968) has developed a one-level information-processing theory which closely parallels the microprocessing level of EPAM. We shall consider Hintzman's version of the microprocessor now and later treat the macroprocessing level with reference to the serial position curve. Hintzman called his information-processing theory the Stimulus and Association Learner (SAL). There are three versions of the theory: SAL-I is the basic theory, SAL-II allows learning on correct response trials, and SAL-III provides for storage of more than one response for each stimulus by using a push-down store system. The basic assumption about memory is that a discrimination net exists, a sorting tree in which each node of the tree is a test of certain aspects of the stimulus input and in which the terminal nodes contain the response or some encoded form of the response called the *image*. The tests at the nodes are based on the letters of the stimulus although other attributes of the stimulus could also be tested.

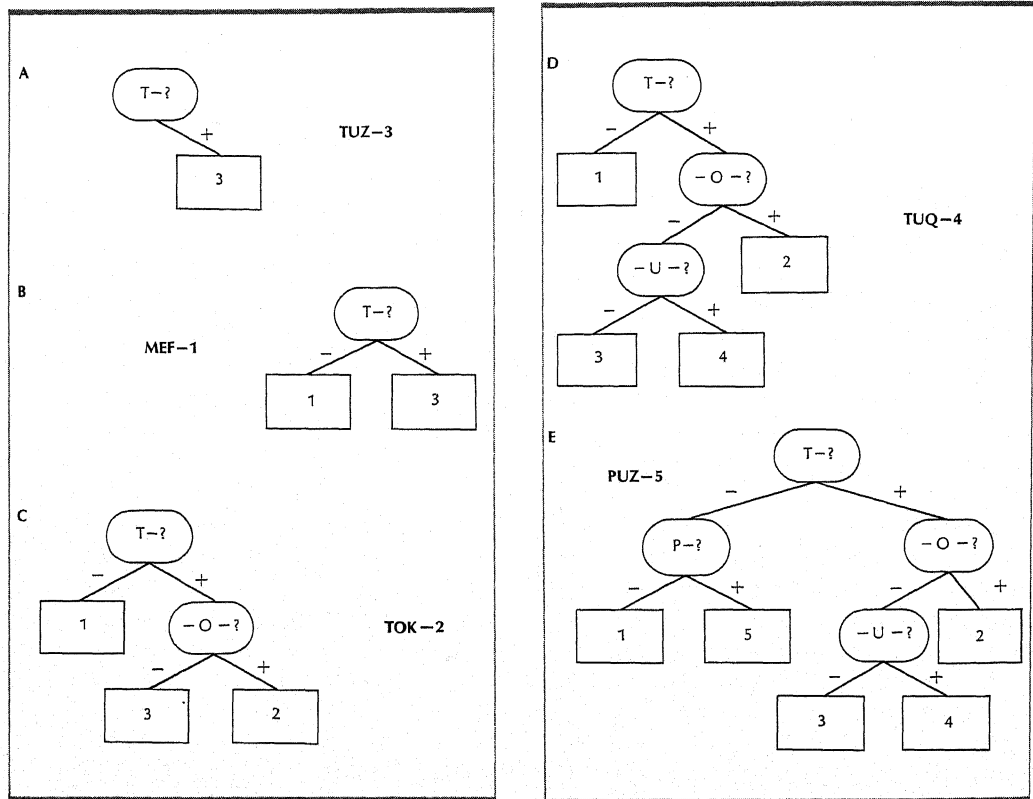
Let us follow through the growth of a tree for a PAL list: TUZ-3, MEF-1, TOK-2, TUQ-4, PUZ-5. Assume that TUZ-3 is the input stimulus to the subject. The subject is assumed first


Figure 20.16. Example of PAL learning according to Hintzman's Stimulus and Association Learner (SAL). As each item in the PAL list is presented, new decision nodes are added to the discrimination net.

to grow a discrimination net on the basis of the first letter. Figure 20.16A shows the net after TUZ-3 is presented. If MEF-1 is presented next, the sorting process leads to a negative branch when the stimulus item is checked for T in the first position, and the response 1 is placed on the negative node (Figure 20.16B). When TOK-2 is presented, a positive branch is followed and leads to the response 3, which is wrong. This sets the process to look at the second letter and test if it is an "O." If it is, then TOK-2 is sorted and the previous response is placed on the negative branch (Figure 20.16C). When item TUQ-4 is presented and is sorted incorrectly on the second letter yielding response 3, another negative branch is inserted so that it can be sorted correctly. Note that when TUZ is next presented it will be sorted to the response 3. Another sort on the third letter will be needed to separate TUZ and TUQ. Figures 20.16D and 20.16E illustrate the tree for the items TUQ-4 and PUZ-5. In the original version of the theory (EPAM), the tree determines the response exactly, but Hintzman has added a probabilistic function in SAL. In particular, he assumes that, after an error, a new node is developed with probability *a*. When, with probability 1 − *a*, the new node is not developed, then, with probability *b*, the new response replaces the old; with probability 1 − *b*, the old response remains.

SAL is not stated as a mathematical theory but rather as a computer program. Thus, fits to data cannot easily be made because methods of estimating parameters are not available. Instead, a reasonable set of parameters (*a* and *b* in this case) is assumed, and the gross characteristics of the data resulting from simulation of a group of subjects are compared with the data resulting from a real experiment. The comparison emphasizes comparable phenomena such as negatively accelerated learning curves, distinct changes in the distribution of the trial of the last error, and so forth. The emphasis is on relating the parameters to the experimental conditions and procedures. Hintzman has investigated the ability of the model to simulate a large number of experiments in PAL and other human learning procedures and has provided a summary list of results of the tests of his theory. He has found that, as predicted by SAL-I, if the list of stimuli is made more similar, the learning is usually made more difficult. With an increased number of alternatives, SAL-I predicts a stationarity type of curve which rises from 1/*r* to a maximum of .5, where *r* is the number of response alternatives. This prediction has been borne out in experiments run by Hintzman (1967). It has been observed that if items are repeated with a varying number of different items presented between the repetitions, massed repetition becomes ineffective (Greeno, 1964). This is predicted by SAL-I because no learning occurs independently of other pairs in the list. The model also correctly predicted faster relearning and transfer effects arising from the similarity between lists. Three predictions failed. One was the effect of "whole," "part," and "repeated-parts" learning methods. The "whole" method exists when the list or set of items is learned all at once. The "part" method exists when the material to be learned is divided into parts and each is learned separately and then recombined. The "repeated-parts" method is present when the first part is learned, combined with the second, and these learned together, then the third part is combined with the first two, and these learned, and so on. Although Postman and Goggin (1966) found the "repeated-parts" method to be more effective, SAL-I did not produce any differences in the three methods. The second failure was the fact that the length of the list proved to have no effect on the learning rate. Calfee and Atkinson (1965) showed that a short-term memory process helped to account for this effect, and Hintzman suggests that a STM process might have to be added to SAL to account for the list-length effect (see below). Finally, SAL-I failed to predict positive transfer in an A-B, A-C

paradigm (see Chapter 21). Hintzman does not know exactly what aspects of SAL-I cause these failures. Certain weaknesses of SAL-I have been corrected by more elaborate versions which we shall review below.

As we have seen, a wide variety of learning experiments have been tested with the SAL model. Although the tests are not quantitative, the fact that certain main effects due to gross variables such as stimulus similarity, number of response alternatives, and massed versus spaced repetition of items are qualitatively handled is impressive. One point that should be emphasized is the similarity between this model and the ideas developed in the general model by Greeno and Scandura (1966). Where Greeno and Scandura talk about encoding, SAL-I relies on the order in which the letters of the stimuli are noticed by the subjects. SAL-I makes a specific assumption about the type of encoding response, whereas Greeno and Scandura leave this less well specified. However, because SAL might require a different encoding rule for a different kind of stimulus, the two theories are really not so different in this respect. A second point of similarity is the fact that errors require a new encoding scheme in both. In SAL-I, another aspect of the stimulus is added, whereas in the general model a new sample of cues is selected. Of course, differences in the combinations of these common ideas make the theories different. The exact differences have not yet been clearly stated; these differences and the useful constructs in each will have to be sorted out in the future.

Hintzman has developed two other models that increase the flexibility of SAL-I. SAL-II was developed to allow overlearning to occur. According to SAL-I, once a verbal list is learned perfectly, no further learning occurs. The perfect learning may involve only the first letter of each stimulus item. In SAL-II, learning can continue to occur on correct trials. After a correct response, the next letter in line in the noticing order is added to the discrimination net with a probability c. This allows the creation of empty terminal nodes. When these empty nodes are encountered later, the model assumes that the subject guesses. SAL-II has been successful in handling results from proactive and retroactive transfer paradigms.

The third version of SAL, SAL-III, introduced a new idea to all-or-none models. The Hullian models had assumed that two responses could be associated with the same stimulus, thus leading to the concept of the habit hierarchy in which various responses would compete with each other. All-or-none models have to assume that either one response or the other is associated to a given stimulus. The SAL-III model assumes a so-called "push-down store" (PDS). At each response node, when a response is stored, the previous response is not erased but is "pushed down." With the passage of time, or with interfering factors, the more recently stored responses are pushed off the stack and lost forever. This process, added in SAL-III, allows better predictions to be made of proactive and retroactive effects with time. In particular, with the passage of time, proactive interference increases and retroactive interference decreases. The assumption of a push-down store also accounts for the effect of distributed practice. The interaction of the PDS and the discrimination net leads to four additional predictions, which further extend the generality of the model: (1) If a subject is simply required to recognize a response among a set of responses, he has a higher probability of being correct than if he has to recall the correct response from memory. SAL-III accounts for this. In recognition, the list at each node is examined and if the item is anywhere on the list, recognition occurs. In recall, the subject does not examine the entire list; only the top item is retrieved. (2) Studies in which second and third guesses are allowed show that the second guesses made by subjects are better than chance; this result can be accounted for by the PDS and the discrimination net (see Binsford & Gettys, 1965). (3) The SAL-III model yields results in good agreement with those re-

ported by Barnes and Underwood (1959) for the modified-modified free-recall procedure. This is a paradigm in which the first-learned list and the second-learned list consist of the same stimulus items, designated A, but with different responses, designated B and C, respectively. This procedure is usually called the A-B, A-C paradigm. When learning the second list, the subjects are asked to give both the B and the C response to the stimulus A. The experimenter can observe the learning of the C responses and the forgetting of the B responses from trial to trial. (4) Finally, Hintzman assumes that the depth of the responses in the PDS determines the latency of a response.

Our summary of the SAL models has been rather cursory, but perhaps we have been able to illustrate the wide range of phenomena that are at least qualitatively predictable by them. Certainly, the results of this approach justify further serious consideration of the information-processing models.

Serial Learning: Specific Issues

Our discussion of PAL involved general questions of response learning, association processes, and stimulus discrimination. The same questions arise in SL, but the analysis of SL has not reached the same level of precision as that of PAL. The major difficulty seems to be defining the functional stimulus in SL. When we do not know what the stimulus is or how to characterize it, the nature of the association process remains very unclear. Furthermore, the fact that the stimuli and the responses are physically the same leads to further problems. If the functional stimulus is determined, is it identical with the functional response? In general, it appears that it is not identical, for the subject must respond in a way isomorphic to the actual physical stimulus in order to demonstrate learning. Finally, there are many facts about SL that suggest that the fundamental notion of forming a S-R bond simply does not work for SL learning.

Earlier we presented a brief view of the Lepley-Hull analysis of SL. Its main features included the idea that the stimulus for item i was the preceding series of items, i-1, i-2, . . . and that this stimulus was associated by trace conditioning with items $i + 1$, $i + 2$, ... Nonreinforcement of the remote associations eventually eliminated error responses due to remote associations. These basic assumptions were interdependent and provided a neat explanation of the serial-position effect. This theoretical view went without serious challenge until the late 1950s. Since that time, however, both the definition of the stimulus and the idea of remote associations have been strongly attacked on empirical grounds.

The functional stimulus in SL The experimental studies conducted to determine the functional stimulus in a list of items learned serially assume a basic similarity between the paired-associate procedure and the serial procedure. A stimulus is presented to which the subject is to make an appropriate response. In serial learning, the response itself becomes the next stimulus. The basic assumption of the Lepley-Hull theory is that an association is formed between adjacent items on a serial list. If serial learning is indeed the formation of a succession of associations, then there should be a large amount of transfer from a list of paired associates A–B, C–D, E–F, . . . when it is relearned as a serial list A–B–C–D–E–F. . . . Likewise, after learning a serial list, transfer to a PAL situation with pairs composed of adjacent items of the serial list should produce positive transfer. Underwood (1963) reviewed a number of studies and raised the question of whether SL is learned as a chain of associations. One of the studies reviewed by Underwood which bears on this issue is an early one by Primoff (1938), who found that a paired-associate list which involved items used as both stimuli and responses, the so-called "double-function list," was extremely difficult to learn. An example of a double-function list is one composed of pairs A–B, B–C, C–D, D–E. A single-function

list of the same items would be A–B, C–D, ... Both could be made into the serial list A–B–C–D–E. A serial list is, according to the chaining assumption, a double-function list of paired associates. Yet, as Underwood points out, a serial list is much easier to learn than a comparable single-function list of paired associates. However, in the paired-associate double-function list, a response item does not occur as a stimulus immediately after it has occurred as a response. Underwood suggests that the difficulty with the double-function PAL procedure may be due to the fact that subjects in the standard PAL procedure tag the stimulus items and the response items differently, whereas the double-function list mixes these tags, thereby causing a large amount of interference. In the serial list, on the other hand, the systematic repetition eliminates the need for tagging.

In a number of experiments (Young, 1959; Jensen, 1962c) designed to study transfer from a paired-associate list to a serial list, some positive transfer has been found. Negative transfer also occurs to an even greater extent (Young, Milauckas, & Bryan, 1963). Thus, subjects can use the associations learned in a PAL task to aid their learning of a related SL task. It should be emphasized that the amount of transfer is not very great.

The second class of studies run to investigate the functional stimulus in serial learning reverses the transfer procedure. First a serial list is learned, and then either a list of single- or double-function paired associates is made from the items of the serial list. One would expect a large amount of transfer if successive items on a serial list were associated. However, Young (1961), Young and Casey (1964), and Jensen and Rohwer (1965) found even less transfer. Nonetheless, in two more recent experiments, Postman and Stark (1967) and Shuell and Keppel (1967) conclude that, although serial learning involves more than a single process, preceding items *are* among the effective functional stimuli. However, in Postman and Stark's experiment, the maximum transfer occurred for a group of subjects who were explicitly instructed about the nature of the transfer task, and they showed only a 61 percent transfer. Another equivalent group of subjects who were not instructed about the transfer procedure showed only 24 percent transfer. It is possible that some of those subjects not instructed saw the nature of the transfer and provided the transfer which did occur. If this was the case, we could argue that a basic association process was not involved, but rather that rule-following behavior might be responsible.

Within the context of stimulus-response theories, there are two major hypotheses concerning the nature of the effective stimulus in SL. The first is that the effective stimulus is composed of some sequence of preceding stimulus items. Exactly how many preceding items are involved and how they enter into the association has not been spelled out. Although Young (1962) did not find support for this hypothesis, Horowitz and Izawa (1963) found that clusters of items could serve as stimuli when the items in the list were not strong associates of each other. The second hypothesis is that the effective stimulus is the position of the item in the list. According to this hypothesis, the subject learns a response to each position. Among the problems with this hypothesis is the fact that subjects have difficulty stating exactly where they are in a serial list at a given point. Further, a serial list can be learned even if each item is presented one position earlier on each successive trial; that is, if trial 1 is A–B–C–D–E, trial 2 is B–C–D–E–A, and so on. In tests of transfer using position as the stimulus cue, there is the possibility that the subject quickly recites the serial list until he finds the stimulus associated with the position, and then relies on this stimulus to respond correctly. However, Ebenholtz (1963a, b) and Young (1962) have produced evidence supporting the interpretation that position is used as a stimulus cue. Two other hypotheses, combining these major hypotheses, have been suggested. One assumes a sequential stimulus for the ends of the list and a positional stimulus for the middle part of the list (Young, Patterson, & Benson, 1963). The other

assumes a positional stimulus for the ends of the list and a sequential stimulus for the middle positions (Ebenholtz, 1963b). Actually, both investigators would allow both types of cues throughout the list but assume that the relative weights of the positional cue and sequential cue change from the ends to the middle of the list.

The difficulty in identifying the stimulus in a serial list is perhaps symptomatic of a serious theoretical flaw. Historically, a number of researchers have raised questions about the explanation that serial learning is based on the associative chain or trace conditioning. Primoff (1938) stated flatly that PAL and SL are different. Lashley (1951), in a brilliant paper which approached serial behavior from a very broad point of view, dismissed the simple chaining interpretation of serial learning. His argument ranged from an analysis of language behavior, through motor responses, to physiological aspects of serial responses. Jensen (1962a, b, c, d) and Jensen and Rohwer (1965) take the view that serial learning is not an associative chain. Jensen's theoretical view is compatible with Lashley's in that both assume that there is a difference between stimulus-response associations and response integration. Instead, they propose that an integrated response is encoded as a single unit and not as a string of stimuli and responses. Furthermore, they suggest that the series of responses is manipulated as a single unit, and an impulse to make a given integrated response is sufficient to evoke the whole serial chain. Presumably, such an integrated response would be learned in a different way than a list of discrete, independent stimulus-response associates. To account for the results of the transfer experiments described above, Jensen relies heavily on the idea of set. If the subject keeps his set of the original learning (PAL or SL), some transfer may occur to the new situation (SL or PAL). However, maintaining a paired-associate set when the task involves serial learning (or vice versa) may, in the long run, cause more learning difficulty. The sets are different, and trying to learn while using the inappropriate set can be very difficult. Jensen feels that the failure to control set in most experiments accounts for the wide range of inconsistent results. One strong piece of evidence in favor of two types of learning is the magnitude of the difference in the difficulty of SL and PAL. A 9-item serial list should have eight associations; yet it is learned as fast as a 4-pair list of paired associates, even when the latter is unpaced and the serial list is presented at 3 sec per item (Jensen, 1962c).

Remote associations Ebbinghaus (1885) first introduced the idea of remote associations. He asserted that every item was associated with every other item in the list and that the strength of the association was inversely proportional to the distance between the items. This basic idea was incorporated into the Lepley-Hull hypothesis and was given a rationale in terms of trace conditioning. Thus, the idea of remote associations is basic to studies of SL, not only because it has existed since the first investigations, but also because it plays a central role in accounting for the serial-position effect. Despite its well-entrenched position in the SL literature, Slamecka (1964) has challenged the basic idea itself. We review his arguments against the experiments supporting remote associations because his arguments lead to a conclusion in accord with the position taken by Lashley (1951), Jensen (1962b), and Feigenbaum and Simon (1962). The three experimental procedures that have been used to support the assumption of remote association are the method of derived lists, the association method, and the method of anticipatory errors (McGeoch & Irion, 1952).

Ebbinghaus' belief in remote associations was based on the procedure of derived lists. A derived list is a new serial list derived from an original serial list by some simple scheme such as taking every other item to form the new list (second order), or taking every third item (third order), and so on. For example, ACEBD is a second-order list derived from ABCDE. If remote associations are formed,

Ebbinghaus argued, then a second-order list would be easier to learn than a third-order list, which in turn would be easier than a fourth-order list. This is the case because, the further that item *i* is from item *j*, the weaker the association between items *i* and *j*. The remoteness of items in an *i*th-order list is *i*. Slamecka makes two crucial points. The first is that Ebbinghaus was his own subject and knew how the lists were constructed. The second point is that many later experiments have failed to show a difference among lists of different orders. Slamecka concludes that the lists are ordered in ease of learning according to remoteness only because the order or rule for making up the list is less likely to be perceived by the subjects if it is more remote. He ran two experiments demonstrating this interpretation very clearly. Thus, the method of derived lists gives the expected results because subjects use a rule to control their performance.

The association method for testing remote associations is quite direct. After a serial list has been learned, each item on the list is presented to the subject, who is to respond with the first item that comes to mind. The response given is coded for its degree of remoteness in the original list from the presented stimulus. Even before Slamecka's analysis, two problems had arisen with this method. One was that the latency of the responses did not correspond with the remoteness analysis, that is, low-order remoteness was not accompanied by short latencies. On the contrary, low-order remoteness was accompanied by longer latencies (McGeoch & Irion, 1952, p. 95). The other problem was the fact that early researchers had used the absolute number of associations to indicate the relationship between remoteness and frequency of response; that is, more remote items occur less frequently (Raskin & Cook, 1937). However, there is an inverse relationship between the degree of remoteness and the number of items at that degree of remoteness. For example, in a list of length *N*, the maximum degree of remoteness is $N - 1$, and there is only one item at that degree. At the $N - 2$ degree of remoteness, there are two remote associations, response $N - 1$ to item 1 and response *N* to item 2. According to Slamecka, correcting for the different absolute number of items at each degree of remoteness yielded a **U**-shaped function instead of the traditional monotonic function. He postulated that these results were due to the relative frequency with which responses had been given in the learning of the serial list. Because of the serial-position function, the items in the middle of the list were not given as responses until near the end of learning. Thus, these items were given as responses only a few times, whereas the items near the ends of the list were given from the very first trial on. Slamecka made up a list in which the items were duplicated in such a way that each item corresponded in frequency to an item from a serial list of the same length. The six items were duplicated 25, 10, 3, 1, 3, and 10 times. Subjects were shown the list of 52 items in a random order and told to look carefully at each. When they were later presented with the items and told to respond with the first item that came to mind, a **U**-shaped function similar to that he had observed in the association method was obtained. Thus Slamecka contended that the method of association does not support the idea of remote associations because the associations can be explained on the basis of past frequency or experience. Although his experiment does not rule out the presence of remote associations, the fact that they can be explained on the basis of a potent variable such as frequency certainly puts the burden of proof on the proponents of remote association.

The method of anticipatory errors considers all error responses made during the learning of a serial list. These error responses can be classified according to whether they are anticipatory or perseverative. Anticipatory errors are those responses to item *i*, but appropriate for a later item, whereas perseverative errors are those made to item *i* but appropriate for an earlier item. In general, very

few perseverative errors are made compared to anticipatory errors; the errors follow the inverse function with respect to remoteness, and they decline with learning. Also, errors made early in learning are likely to be more remote than errors made later on in learning.

Slamecka did not accept the findings described above (which were confirmed in his own experiments) as support for the idea of remote associations. Instead, he argued that the findings reflect the fact that the subject must learn the items themselves. In the beginning, only the first few and last few items are known. Because the subject has just seen the most recent items, he does not guess these when he is asked to guess what items will occur next; instead, he guesses from the other items he knows, which are likely to be those at the end of the list. Thus, early in learning, many high-order remote associations relative to the total number of remote associations are produced. As learning increases, the subject's uncertainty decreases, and the middle items are the only ones he remains uncertain about. Responses from the middle of the list to stimuli from the middle of the list must be of a relatively low order of remoteness. This is a plausible explanation for the change in the relative frequency of high- and low-order remote associations which does not require the assumption of remote associations.

Needless to say, such an uncompromising attack on so fundamental a principle has not gone without a counterattack. Dallett (1965) and Bugelski (1965) contend that there are flaws in Slamecka's arguments and that he has gone too far in his conclusions. Nonetheless, when we consider Slamecka's arguments along with the difficulties encountered in identifying the stimulus in serial learning, doubts about the traditional view must inevitably arise. We can conclude by presenting an information-processing model which seems to be in accord with the newer approach to serial learning.

The serial-position curve—an information-processing explanation The serial-position function plots some measure of the number of errors against the items according to the position of the items in the list. It has been found that the curve rises to a maximum point just past the middle item of the list and then declines again. Usually the last item causes more errors than the first—about the same number of errors as for the second item. Historically, the practice had been to plot the
Figure 20.17. Serial-position effects in lists of 14 nonsense syllables and in (easier) lists of 14 familiar names. The left figure, plotted in terms of the absolute numbers of errors, seems to show a much more marked piling up of errors in the middle of the more difficult list (quite in accordance with the inhibition theory). But when the errors in each serial position are expressed as percentages of the total number of errors for the whole list, the two curves appear identical. (McCrary & Hunter, 1953.)

absolute number of errors, but McCrary and Hunter (1953) found that if they plotted the percentage of the errors at each position relative to the total number of errors (as in Fig. 20.17), absolute error curves of very different levels and shapes became identical (with the same length list, of course). Thus, over a wide range of variables, relative errors at each position remain constant. However, as Feigenbaum and Simon (1962) have pointed out, there are ways of distorting the shape of the serial-position curve. If one item is made clearly distinct from other items (Von Restorff effect), it will be learned much faster. Or, for example, if half the list is colored red and the other half black, the curve shows a large decrease in errors on the last item of the red half of the list and the first item of the black half. This occurs right at the point where the maximum number of errors is usually observed (Wishner, Shipley, & Hurvich, 1957).

On the basis of these and a few other facts about the serial-position curve, Feigenbaum and Simon have developed their information-processing theory of serial learning. Earlier we presented Hintzman's information-processing theory for rote learning, which is a modified version of the microprocessing system of the Elementary Perceiver and Memorizer (EPAM) first introduced by Feigenbaum (1959). The original theory also contained a macroprocessing system which worked in conjunction with the microprocessing system. The serial-position effect is primarily accounted for by the macroprocessing system. We discuss the macroprocessing system here and the reader can see how the microprocessing and macroprocessing systems interact. We follow the Feigenbaum and Simon paper (1962). (The reader should refer to page 975 for a review of information-processing models.)

Postulate 1. Serial mechanism. The central processing (CP) mechanism is assumed to be serial, that is, it processes one item at a time. When, as in SL or PAL, many items require processing, the CP takes them in some order.

Postulate 2. Fixed processing time. Each item requires a fixed amount of time to be processed. (At this point, the microprocessing aspect of the general theory comes in. Each item selected by the CP must be sent through a discrimination net such as that described in the Hintzman model. The time required for this process may vary but has some fixed minimum. The CP must allow enough time for the item to be sorted through the discrimination net.)

Postulate 3. Immediate memory. An immediate memory or short-term memory system holding about seven basic "chunks" is assumed. To apply the theory here, we have to postulate what the basic unit of analysis is for the subject. For most nonsense-syllable work, Feigenbaum and Simon consider the letters of the syllables as basic units; about six letters or two CVC nonsense syllables can be contained in the memory buffer. They are not very explicit about the duration of items in the STM, but presumably if they decay in time, CP can restore or rehearse them so that, if no new items are presented, the six items remain permanently in STM.

Postulate 4. Anchor points. This very basic postulate of the system has been added primarily to handle SL and the serial-position curve. An anchor point is related to the idea of attention. It is assumed that certain stimulus items are selected by the subject in order to provide a point of reference for other items. For serial learning, the attention is assumed to be focussed on specific items or positions of the list, items at the so-called "anchor points." In the ordinary SL task, before any learning, these anchor points are at the first and last items. Feigenbaum and Simon assume that the items are learned in a systematic way. Once the first and last items have been learned, they in turn define anchor points for items adjacent to them. For the serial-learning task, another, more specific assumption is made. It states that the first and second items are learned first. Then either the third or the last item is learned, each with probability $\frac{1}{2}$. If the third is learned, then the

fourth or last is picked for learning, again each with probability $\frac{1}{2}$. This particular mechanistic ordering of how items are learned produces a very reasonable serial-position curve (Feigenbaum & Simon, 1961).

Although response-learning and guessing factors must be brought into the picture (Slamecka's ideas are relevant here), the basic processing of the system gives a good account of most facts known about the serial-learning curve. The effects of coloring different parts of the list, or of introducing some salient cue to a single item, are incorporated into the scheme by assuming that they change the anchor points. Feigenbaum and Simon note that their theory is an all-or-none theory and treat Rock's and Estes' results as consistent with theirs. Feigenbaum and Simon feel that their theory, in both its microprocessing and macroprocessing versions, represents a new approach to verbal learning.

The successes of information-processing theories do not invalidate all earlier conditioning-type theories. Rather, they indicate that learning processes can be analyzed at a number of levels. Different theories may be needed at different levels. Perhaps for higher-level analyses, we need theories such as the information-processing theories with their memory, attentional, and organizational processes. The role of variables such as frequency may be handled by the conditioning theories. Ultimately, we may hope for an integration of the findings from all levels.

TRANSFER, INTERFERENCE AND FORGETTING*

21

Learning is a cumulative process. The more knowledge and skills an individual acquires, the more likely it becomes that his new learning will be shaped by his past experiences and activities. An adult rarely, if ever, learns anything completely new; however unfamiliar the task that confronts him, the information and habits he has built up in the past will be his point of departure. Thus transfer of training from old to new situations is part and parcel of most, if not all, learning. In this sense the study of transfer is coextensive with the investigation of learning. However, it is only when the conditions of prior training are brought under experimental control that the contributions of transfer can be precisely evaluated. Experimental studies of transfer are, therefore, concerned with the influence of circumscribed learning experiences on subsequent performance in specific test tasks. It is clear that experimentally produced effects represent at best only a small fraction of the total transfer from past training which the individual brings to the test situation. Manipulation of the subject's learning history on a limited scale may nevertheless permit the identification of some of the dimensions and mechanisms of transfer.

*The material considered in this chapter is restricted to studies of verbal learning and memory.

Nature of Transfer Effects

A study of transfer is by definition a two-stage experiment comprising a training phase and a test phase. The basic question is how the training provided during the first stage influences performance during the second stage. The observed effects may be zero, positive, or negative: The prior activity may fail to influence performance in the test situation, facilitate it, or interfere with it. The presence of significant transfer effects, whether positive or negative, implies that at least some of the responses established during the training phase are carried over to the test task. The effects are positive or negative depending on whether these responses are appropriate or inappropriate in the new situation. The emphasis in the formulation and interpretation of experiments on transfer is, therefore, on the similarities and differences in the requirements of the successive tasks.

What tasks are functionally similar depends on the nature of the dispositions that the individual carries over from one situation to the next. Historically, theoretical controversy centered on the question of the breadth of the changes produced by practice. At one extreme was the doctrine of formal discipline, which held that such "faculties" as memory, judgment, and reasoning could be strengthened by exercise on the appropriate materials. Learning tasks were considered to be similar to the extent that they called for use of the same faculty. Mathematics and law both engage the individual's power of reasoning, so that training in one of these subjects should be a preparation for success in the other. This view had, of course, a profound influence on the development of school curricula. Diametrically opposed was the theory of "identical elements," espoused by Thorndike (1903), according to which the amount of transfer is determined by the degree to which performance in successive situations depends on the same associative connections.

Early experimental studies designed to decide between the opposed conceptions of transfer appeared to give clear support to the theory of identical elements. A few relevant studies are summarized below. Today the controversy in its original form is largely of historical interest. In the context of empirical investigations of transfer the concept of mental faculty was intractable to manipulation and measurement. The theory of identical elements insisted that transfer effects reflect concrete and circumscribed changes in behavioral tendencies; in that sense the theory gained wide acceptance, even though Thorndike's description of the elements lost its currency. From a historical point of view it is interesting to note than Thorndike's position was not as "atomistic" as the notion of identical elements implies. He suggested that among the major components of transfer are "ideas about aims and ideas of method and general principle" as well as "associations involving elementary facts of experience" (1903, p. 81). In modern studies of transfer it has remained useful to maintain a distinction between the transfer of general principles or strategies of learning on the one hand, and of specific associations on the other.

Transfer as a Measure of What Is Learned

Instead of focusing on the cumulative effects of practice one may use the transfer test as an analytic device for determining what has been learned in the training phase. When a task is mastered under controlled conditions of practice, interpretative questions often arise about the nature of the habits or dispositions that the subject acquires and that allow him to satisfy the experimental requirements. To answer such questions we construct transfer tasks that distinguish between alternative hypotheses about what has in fact been learned. The procedures used to determine the functional stimulus in paired-associate learning will serve to illustrate this use of transfer tests and at the same time exhibit the limitations on the conclusions that can be based on the results of such tests.

Suppose a subject learns a paired-associate list in which the stimuli are compounds com-

posed of distinctive elements, such as nonsense syllables presented against colored backgrounds; the responses are words or digits. When the subject has mastered the list, the question remains open as to how many responses were associated with single elements (syllables or colors) rather than with the total compounds. As long as the elements are consistently paired, the subject can use one of the components as the cue to the correct response and disregard the other component. The compound is the nominal stimulus defined by the experimenter, but one of the elements may be selected as the functional stimulus by the subject (see Underwood, 1963). The extent to which such stimulus selection has occurred is determined by means of transfer tests in which the subject is required to give the prescribed responses to one or the other of the elements, such as syllables alone or colors alone, or to the total compound. The available evidence shows clearly that the more meaningful element will, in fact, be selected in the majority of cases. In the transfer phase the colors alone are as effective as the total compound in eliciting the correct responses, whereas performance drops to an extremely low level when the syllables alone are presented (Underwood, Ham, & Ekstrand, 1962). It must be recognized, however, that transfer tests for cue selection provide information only about the stimuli which are functional at the end of practice. Stimulus selection that occurs early in learning but is abandoned in the later stages of acquisition will not be detected by such tests. It has, in fact, been found that subjects who practice cue selection up to the point of the initial mastery of a list begin to develop associations to the nonpreferred, redundant elements of the stimulus during a period of overlearning (James & Greeno, 1967). To obtain information about the course of selection, transfer tests would have to be administered after varying amounts of practice. The basic point here is that tests of transfer can be used to determine what has been learned after a given amount of training but usually yield far from conclusive information about how the terminal stage of mastery was achieved.

We have identified two general objectives of experimental studies of transfer: the assessment of the effects of prior training on the mastery of new tasks and the determination of what has been learned as a result of a given learning experience. The two problems are, of course, closely interrelated. There is, however, an important difference in emphasis between the two types of experiments. In one case the focus is on the conditions of improvement in the test stage. In the other case the characteristics of the first task are under investigation. The characteristics of interest, such as stimulus selection, may or may not be related to efficiency of performance.

Relation of Transfer to Interference and Forgetting

In the history of research on verbal learning the study of transfer and the analysis of the process of forgetting have been closely linked in terms of both experimental operations and theoretical interpretations. This continuity becomes readily apparent when we consider the classical paradigm of negative transfer in which different, unrelated responses are successively learned to the same stimuli (*A–B, A–D*). Under these conditions the prior acquisition of *A–B* usually retards the formation of the association *A-D*. In addition, the association of different responses to the same stimulus serves to impair the retention of both the first and second task, as compared to appropriate control treatments in which a single list is learned and recalled. Thus, there are negative transfer effects attributable to associative interference in the learning of *A–D*, retroactive inhibition of *A–B*, and proactive inhibition of *A–D*. Because they are produced by the same experimental operations, negative transfer and interference in recall came to be viewed as complementary manifestations of the same underlying process (McGeoch, 1942). Moreover, since it was possible to control the amount of forgetting in

the laboratory by manipulating the conditions of prior and interpolated learning, it was parsimonious to infer that all forgetting is the result of habit interference (McGeoch, 1932a; Underwood & Postman, 1960). That is, whether forgetting occurs inside or outside the laboratory, interference between successive learning activities may be responsible for the retention losses. The interference hypothesis has not only been highly productive of empirical research but has also occupied a focal position in theoretical discussions of forgetting. Thus interference theory provides a convenient point of departure for a discussion of the phenomena of forgetting. It is because of these theoretical and empirical continuities that the problems of transfer, interference, and forgetting are considered together in this chapter.

DESIGN OF TRANSFER EXPERIMENTS

The basic question that an experimental study of transfer is designed to answer is whether and in what ways the manipulated conditions of prior training influence performance in a test task. Let *A* represent the training phase and *B* the test phase. The desired information is provided by the comparison of an experimental and a control group:

	Training	*Test*
Experimental	*A*	*B*
Control	—	*B*

The test task is the same for the two groups; the difference between the two treatments lies entirely in the presence or absence of prior training. As in any other experiment, the validity of the conclusions about the effects of the independent variable depends on the comparability of the groups subjected to different treatments. To obtain groups of equal ability the investigator must rely on appropriate sampling procedures and random assignment of subjects to conditions. It is also possible to equate subjects on characteristics known or presumed to be related to performance in the critical task.

The control group is represented as receiving no prior training. A more precise statement is that the activity of the control group is not manipulated before the test on *B*. Actually these subjects engage in a variety of activities during the period preceding the test that are assumed to be irrelevant to their subsequent performance (see Murdock, 1957, p. 314). (The same is true for the activities of the experimental subjects prior to the start of training, but our present concern is only with the period immediately preceding the transfer test.) A more complete description of the design is, therefore, as follows, where *X* stands for unknown and presumably irrelevant prior activities:

	Training	*Test*
Experimental	*A*	*B*
Control	*X*	*B*

A difference between the experimental and the control group in the performance of *B* permits the inference that *A* is a source of transfer. The exact nature of the transfer effect cannot, however, be specified. Training on *A* may not only establish specific habits that are carried over to *B* but may also serve to adapt the subject to the experimental situation and the requirements of the learning task. The observed transfer is, therefore, likely to reflect a combination of nonspecific and specific habits and skills acquired during the training phase. When interest centers on the specific transfer effects attributable to the similarity relations between successive tasks, nonspecific practice must be given to the control group. If *N* is a task assumed to provide such practice, the design takes the form:

	Training	*Test*
Experimental	*A*	*B*
Control	*N*	*B*

If both control conditions (*X* and *N*) are included, the difference between them provides an estimate of the nonspecific or general transfer effects. The choice of task *N* will depend on the investigator's assumptions about the potential sources of nonspecific transfer from task *A*. Whenever possible, tasks *A* and *N* should be equivalent in all respects except for the specific similarity relations to *B*. Thus, in studies of transfer between lists of paired associates both the stimulus and the response terms of the training list (*N*) in the control condition are unrelated to those in the test list (*B*), whereas there is a specified degree of similarity between the units in the two tasks (*A* and *B*) in the experimental condition.

The similarity relations between successive tasks may be such as to make it an arbitrary matter in which order the two activities are carried out. That is, with respect to the variables under study the experimental sequences *AB* and *BA* are equivalent. A typical example is provided by two lists of paired associates in which the stimuli are the same but the responses are unrelated. The variable defining the condition of transfer is the relation between the successive responses. If the same rules are used in the construction of the two lists, there is no basis for distinguishing between the alternative sequences. For purposes of increasing the generality of the findings, it is advisable to use both sequences equally often in a balanced design. It is possible, of course, that for unknown reasons the observed transfer effects may not be strictly symmetrical; whatever differences between the two sequences are found would have to be attributed to uncontrolled sources of error. Under these circumstances it is possible to dispense with the control group if the investigator's interest is limited to the question of whether or not there is a net transfer effect. With half the group learning the tasks in the order *AB* and the other half in the order *BA*, each subject serves under both a control and an experimental treatment, and the two acquisition functions can be compared directly.

The situation changes when the successive tasks are known not to be equivalent, as, for example, when they differ in difficulty or in response requirements. Contrary to what has been implied in the literature, it is not appropriate to balance the order of tasks and pool the results for the two sequences under these circumstances. The design in question is usually presented in the following form:

	Training	*Test*
Group I	*A*	*B*
Group II	*B*	*A*

The difference between the training phase and the test phase for the combined groups is then used as a measure of the net change attributable to prior practice. The basic objection to this design is that transfer effects cannot be assumed to be symmetrical when there are systematic differences between tasks. Pooling the results for the two groups may, therefore, mask significant effects associated with order. For example, transfer is not symmetrical between serial and paired-associate learning when the sequential order of items is preserved in the successive lists (Young, 1959). Whenever the task requirements in the training and in the test phase are not equivalent, the transfer effects in each direction—from *A* to *B* and from *B* to *A*—must be evaluated separately.

In light of the preceding discussion it will be useful to distinguish explicitly between two cases of counterbalancing of tasks in a transfer design. When the tasks are equivalent, counterbalancing represents a sampling of conditions and increases the generality of the conclusions. Failure to obtain symmetry of transfer contributes to the unexplained error variance. When the tasks are not equivalent, counterbalancing has the effect of averaging out differences associated with the order of practice, that is, it serves to eliminate systematic sources of variance from consideration.

The designs discussed so far apply to situations in which new tasks, presumably encountered by the subject for the first time,

are practiced in both stages of the experiment, such as successive lists of paired associates in studies of verbal transfer. Such studies are categorized as employing the method of successive practice; the dependent variables are measures of acquisition of the test task. Historically, experiments on transfer have also been concerned with the effects of practice on abilities which the subject brings to the experimental situation but which are capable of improvement. In order to evaluate the effects of practice on such abilities, both the initial and the terminal level of performance must be assessed. When the degree of change in an existing ability is the dependent variable, the experimental design characteristically has the following form:

	Pretest	*Training*	*Posttest*
Experimental	*A*	*B*	*A* (*A′*)
Control	*A*	*X*	*A* (*A′*)

The tasks used in the pretest and the posttest must be either identical (*A*) or strictly equivalent (*A* and *A′*). The experimental group is given practice on *B*, whereas the control group is not; the latter engages in irrelevant activities (*X*), which may or may not be prescribed by the investigator. The administration of the pretest makes it possible to determine the initial comparability of the groups; in many investigations the experimental and the control subjects are matched on the basis of the pretest. If the match is perfect, the difference on the posttest provides a direct measure of transfer; if there are initial differences, the amounts of change are compared.

A widely recognized shortcoming of this design is the practice afforded by the pretest, which by itself is likely to result in improved performance on the posttest. It is true that the gains attributable to the pretest should be equal under the experimental and the control treatment, so that there is no bias in the evaluation of the transfer effect. However, if the practice curve for the ability under study is negatively accelerated, the pretest may account for a substantial proportion of the total possible improvement, and the measure of transfer becomes relatively insensitive to the effects of additional practice. Another difficulty was pointed out by Solomon (1949): The pretest may not only permit practice on the test task but may also have a direct influence on the effectiveness of training under the experimental condition. Taking the pretest may affect the subject's set and may serve to activate either correct or incorrect response tendencies, which are carried over into the training phase. The net effect of the pretest on training may thus be either beneficial or detrimental. The influence of training per se cannot, therefore, be assessed unequivocally by the difference between the experimental and the control group on the posttest. In order to take account of this possible source of bias, Solomon suggested the addition of a second control group to the conventional design:

	Pretest	*Training*	*Posttest*
Experimental	*A*	*B*	*A*
Control I	*A*	*X*	*A*
Control II	*X*	*B*	*A*

The second control group goes through the training phase and receives a posttest but is not given a pretest. For purposes of analysis the best estimate of the pretest performance of control group II is the grand mean of the scores of the other two groups. The change between the observed posttest score and the inferred pretest score represents the effects of practice per se, whereas the change for control group I measures the influence of the pretest. If the change score of the experimental group fails to equal the sum of the change scores for the two control groups, a systematic effect of the pretest on the effectiveness of the training procedure is indicated. Solomon reports the results of a demonstration experiment in which the three-group design was used. The noteworthy finding was that the pretest appeared to have an adverse

influence on the results produced by practice, that is, the conventional two-group design would have led to an underestimation of the amount of improvement attributable to training.

It has been customary to describe a number of alternative experimental plans for the investigation of transfer. The present discussion suggests that the options with respect to design are quite limited. When the effects of prior training on new learning are under study, the *same test task* must be used under the experimental and the control treatment. There may, of course, be a number of different experimental treatments; the requirement of a common test task obtains with equal force in such cases. There are circumstances in which the characteristics of the materials, for example, the associative relations between items in successive lists, make it expedient to use different test tasks. If that is done, the tasks must be shown to be strictly equivalent in difficulty, so that the test-stage requirements may be assumed to be the same under all conditions. Thus, most acceptable designs reduce to the basic format illustrated by the comparisons of *AB* with *XB*, and *AB* with *NB*. When interest centers on improvement in an existing ability, the use of pretests is necessitated. These tests must, of course, be equivalent and the same under all treatments.

MEASUREMENT OF TRANSFER

Let us return to the basic design in which the sequence of events is *AB* under the experimental treatment and *XB* under the control treatment. The direction and amount of transfer are measured by the difference in performance between the two groups on the common test task *B*. Transfer can be measured at any or all points in test-task learning for which data are available. As a practical matter it is advisable to carry practice on the test task to a high performance criterion or for a substantial number of trials. It is then possible to determine both the initial level of facilitation or interference and the changes in transfer effects that develop in the course of acquisition.

There are a priori reasons for expecting measures taken early in test-task learning to be maximally sensitive to transfer effects. The difference in prior experience between the experimental and the control group is greatest at the beginning of the second stage. The two groups are treated alike during the acquisition of the test task, and the relative weight of the earlier training will diminish as test learning continues. It must be recognized, however, that much will depend on the components of performance that are carried over from the training to the test phase. If the previously acquired habits first come into play relatively late in the acquisition of the test task, the manifestation of significant transfer effects will be correspondingly delayed. In some cases prior training is a source of both facilitation and interference, and the opposing influences may come to the fore at different points in the acquisition process, so that the sign of the transfer effects changes in the course of test-task learning. It is clear that there can be no general rules specifying the points in test-task learning that should be considered in the determination of transfer effects. Nevertheless the likely importance of measures obtained early in acquisition is worth emphasizing, especially in view of the fact that there is sometimes an undue reliance on criterial measures. For example, in verbal learning a criterion of mastery not only represents a chance peak in a fluctuating curve of performance (Melton, 1936), but the time required to attain it also depends heavily on the speed of acquisition of the most difficult item in the list. Thus criterial measures are peculiarly insensitive to transfer effects and in fact often yield null results when there are significant differences between treatments early in learning (see Postman, 1968a, p. 565).

For any given performance measure, for example, the number of correct responses in a fixed number of trials on the test task, the difference between the experimental and the

control group expresses the amount of transfer in terms of raw scores. One limitation of such a score is that it is not comparable from one study to the next if there are variations in the scale of measurement or the level of attainment. It is common practice to translate the absolute difference scores into measures of relative transfer. A widely used index of relative transfer is the percentage of improvement shown by the experimental group over the control group:

$$\text{percent transfer} = \frac{E - C}{C} \times 100$$

where E and C are the scores of the experimental and the control group, respectively. If the scores vary inversely with level of performance, for example, when the dependent variable is the number of trials to criterion or a count of errors, the difference $C - E$ is used in the numerator. The same formula can be applied to measures of change between a pretest and a posttest.

Unfortunately, such percentage measures are no more comparable than the raw difference scores if they are based on different units of measurement. If the control group makes 10 errors in one task and 100 errors in another, 50 percent transfer—a reduction to 5 errors in one case and to 50 errors in the other—does not necessarily signify equivalence of practice effects. If the learning curves for the two tasks have different shapes, the percentages obviously do not have the same meaning. In light of these considerations Gagné, Foster, and Crowley (1948) proposed a relative measure that expresses the difference between the experimental and the control treatment as a percentage of the maximum score that can be achieved in the test stage. The maximum score can often be specified in advance, for example, zero errors in the recitation of a list or attainment of the criterion of mastery on the first test trial. In other cases the maximum has to be determined empirically; for example, the highest score achieved by any of the groups in the experiment over the specified period of practice is used (Gagné & Foster, 1949). The proposed formula is

$$\frac{E - C}{T - C} \times 100$$

where T is the maximum possible score in the test stage. The advantage claimed for this formula is that it "makes use of a scale of improvement the limits of which are determined," that is, the zero point is defined by the initial score of the control group, which received no prior training, and the 100 percent point by the maximal value attainable in the test. It should be apparent, however, that the problem of comparability is no more solved by this means than it is by the use of the earlier formula. As Gagné et al. recognized, the units of the scale cannot be assumed to be equal because the curve of acquisition is likely not to be linear but rather negatively accelerated. When the C scores are at different distances from the maximum, a direct comparison of percentages may be misleading. The authors also acknowledge the fact that the index becomes ambiguous when transfer is negative because there is no way of defining maximal possible interference analogously to total possible improvement. The shortcomings of this measure of relative transfer have been discussed in some detail by Murdock (1957), who emphasizes the point that the determination of the limits of improvement is often difficult or of questionable validity. Murdock himself suggested a modified formula which yields symmetrical values of positive and negative transfer, with the upper limit at each end of the scale equal to 100 percent:

$$\text{percent transfer} = \frac{E - C}{E + C} \times 100$$

This formula, like the others, does not resolve the problem of comparability of units if the results of different studies are to be compared.

A final example may serve to illustrate this difficulty. Suppose a 10-item list is used as the

test in one study, and a 20-item list in another study. The scores obtained on the initial test trial are as follows:

	10-item list	*20-item list*
E	5	7
C	2	4

The absolute amount of transfer is the same for the two tasks. By the conventional transformation the percentages of transfer are 150 for the 10-item list and 75 for the 20-item list. The formula of Gagné et al. yields 37.5 and 18.8 percent, respectively, and Murdock's formula 43 and 27.3 percent. The three indices are of strikingly different magnitudes but agree in showing about twice as much transfer for the short as for the long list. However, the psychological implications of this finding are far from clear. It cannot be inferred that the reduction in effort is twice as great for the 10-item as for the 20-item task because the amount of study time per item required for a given probability of recall increases with length of list. There is obviously no implication that the training and test task are twice as similar in one condition as in the other. In fact, the difference in percentages does not appear to entail any determinate conclusions about the transfer process in the two situations. Complementary ambiguities develop when trials or time to mastery is the dependent variable. When control groups differ in ability or in level of attainment, the uncertainties of interpretation parallel those created by variations in task difficulty.

The difficulties inherent in the use of relative measures have been recognized but apparently have not been viewed as decisive. A re-examination of these problems has led us to the conclusion that inferences from percentage measures must remain ambiguous when there are substantial differences in task difficulty or ability level among the studies to be compared. There is, indeed, a risk that the use of transformations into relative terms may draw attention away from the systematic effects of such variables as task difficulty or ability level or lead to incorrect conclusions about the influence of such variables. It is not apparent that the use of percentage measures has promoted the discovery of important functional relations in transfer. In fact, the frequency of use of such measures has declined in recent years, certainly in the field of verbal learning. Relative measures may have practical value in certain situations in which interest centers on the most efficient utilization of available training time; they should be used with extreme caution, if at all, in the examination of theoretical issues in transfer. Absolute measures reflect directly the outcome of experimental observations and convey unequivocal information. For these reasons they are to be preferred in principle to derived measures. Conclusive comparisons among experiments can rarely be achieved by the projection of scores onto a common scale; rather such comparisons are a primary task of systematic theoretical analysis.

INTERFERENCE DESIGNS

We turn now to a consideration of the designs used in the study of interference at recall. There are two basic designs representing the experimental arrangements for the measurement of retroactive and proactive inhibition, respectively.

Retroactive Inhibition

Retroactive inhibition refers to the detrimental effects on retention of a learning activity interpolated between the end of acquisition and the test of recall. The standard design has the following form:

	Original learning	*Interpolated learning*	*Recall*
Experimental	Yes	Yes	Yes
Control	Yes	No	Yes

In the application of this design it is essential that the experimental and control groups be strictly comparable and treated in the same way except for the nature of the activity filling the interval between learning and recall. In particular, degree of original learning and length of the retention interval must be strictly equivalent. With respect to the critical manipulated variable, the control condition is defined in a negative way: It does not engage in interpolated learning. For this reason the control treatment is often designated as the rest condition. In practice, rest means some activity that is judged to be entirely irrelevant to the experimental task. A variety of filler activities has been used: working puzzles, solving arithmetic problems (when the learning materials are verbal), rating cartoons, and so on. It is clear that the designation of such tasks as irrelevant is based on the assumption that interference will develop only if there is some determinate degree of similarity between the original and the interpolated activity. To the extent that this assumption is false, the control treatment fails in its purpose.

A further caution that must be borne in mind concerns the possibilities of uncontrolled rehearsal. If the control subject is not fully and continuously occupied by the filler activity, he may engage in rehearsal of the original task. Such uncontrolled rehearsal introduces a bias in favor of the control group in the assessment of the recall results. There has been little evaluation of the effectiveness of different rest activities, although this problem has begun to receive some systematic attention in recent studies of short-term memory. It is likely that differences between rest activities contribute to the variation in findings from one experiment to the next.

It will undoubtedly have been noted that the formal structure of the experimental design for retroactive inhibition is identical with the transfer design in which pre- and posttests are used. The first stage, however, is no longer defined as a test of pre-experimental proficiency which may incidentally function as a practice period; rather it is the phase during which the critical habits are established under controlled conditions. (This does not rule out the possibility, of course, that the acquisition of the experimental tasks is influenced by pre-experimental habits.) The interaction between the first and the second stage, to which Solomon called attention, now is not an uncontrolled source of variation but rather one of the very processes the experimental operations are designed to assess.

If recall is higher for the control than for the experimental group, the difference defines the amount of retroactive inhibition (*RI*), that is,

$$RI = C - E$$

On the other hand, if the experimental group surpasses the control group, that difference defines retroactive facilitation; in this case $C - E$ is a negative rather than a positive quantity. As in the case of transfer, percentage measures have frequently been used, again with a view to permitting comparisons among the results of different studies. The usual formula is

$$\%RI = \frac{C - E}{C} \times 100$$

The difficulties of interpretation posed by such relative measures are the same as before. Thus, when the *C* and *E* scores are 2 and 1 in one case, and 10 and 5 in another, we obtain 50 percent *RI* for both, but the psychological implications may be quite different. If the maximum possible is taken to be 10 in both cases, the degree of learning of the items which failed to resist interference is clearly not comparable. That fact is, of course, of critical importance in the interpretation of the results. It is also obvious that the percentages become increasingly unstable as the control baseline becomes smaller. In the rather extreme case we have chosen for illustrative purposes, the loss of a single item, which may not be a reliable observation, represents 50 percent *RI*. The example is not, however, as far-fetched as it may seem, since

TABLE 21.1

	Prior learning	*Test-task learning*	*Retention interval*	*Recall*
Experimental	Yes	Yes	Yes	Yes
Control	No	Yes	Yes	Yes

bases of this order of magnitude have, in fact, been frequently used in the calculation of percentages of *RI*. Again the absolute measure is to be preferred because it remains close to the experimental observations and because it does not permit the investigator to ignore systematic differences among experiments.

Proactive Inhibition

Proactive inhibition refers to the detrimental effects of prior learning on the retention of subsequently learned materials. As such it should be distinguished sharply from negative transfer effects in acquisition. The standard design is shown in Table 21.1. Note that there is a retention interval between the end of test-task learning and recall. To satisfy the requirements of the design, this interval must be longer than that between successive trials in acquisition. Given this definition, proactive inhibition, if it occurs, must necessarily be some increasing function of the time since the end of learning. As long as that time is equal to or shorter than the intertrial interval, acquisition will presumably continue to a maximum. When the interval exceeds that critical length, there is an opportunity for forgetting to set in and for the interfering effects of prior learning on retention to manifest themselves.

As in the case of retroactive inhibition, the logic of the design calls for equal treatment of the experimental and the control groups except for the manipulated condition of prior learning. However, reference to the temporal arrangements of this design reveals a difficulty that was not present in the earlier case. For the experimental group, the test task is the second phase of practice; for the control group, it is the first. Consequently, the experimental subjects acquire the test task under more favorable conditions than do the control subjects; the former, but not the latter, have had an opportunity to become habituated to the situation and to develop general learning skills.

Carrying the two groups to the same criterion of performance does not necessarily resolve the difficulty because associative strength at criterion is likely to be greater for the group that learns faster. It is possible to equate the amount of prior experience for the two conditions by having the control group learn an unrelated task; as we have already seen in discussing the problem of a rest interval, the designation of an activity as irrelevant or unrelated depends on assumptions about the range of similarity relations between successive tasks that are capable of producing interference; but that is precisely one of the questions studies of proactive inhibition are designed to answer. While these sources of uncertainty are inherent in the design, they usually do not constitute insuperable difficulties. The magnitude of the bias favoring the experimental group in acquisition can often be assessed and taken into account. If prior practice is equated, proactive interference under various experimental treatments can be evaluated relative to a stable control baseline.

The considerations which bear on the measurement of proactive inhibition parallel those already discussed for retroaction. The amount by which the recall of the control group exceeds that of the experimental group provides a measure of proactive inhibition (*PI*):

$$PI = C - E$$

If the difference favors the experimental group, we speak of proactive facilitation. The difficulties posed by the use of percentage

measures are the same as before. Finally, it should be noted that in the interest of simplicity of exposition only a single experimental condition was included in both the interference designs. The problems of control and inference remain the same when there are multiple experimental treatments.

NONSPECIFIC TRANSFER: ABILITY TRAINING

As was noted above, early experimental studies of transfer were stimulated by the growing skepticism with which psychologists came to view the doctrine of formal discipline. Interest centered on the question of whether there was transfer of training between tasks that presumably engaged the same mental function, for example, the ability to memorize or to make sense discriminations. We shall review a few of the classical experiments bearing on this problem, with special emphasis on the work concerned with memory training. These studies are not only of historical interest, but they can also be seen as being in a direct line of continuity with contemporary investigations of nonspecific transfer.

The first phenomenon of transfer to be investigated experimentally was cross-education, that is, the spread of the effects of training from one part of the body to its symmetrical counterpart. Changes between a pretest and a posttest were used by Volkmann (1858) to measure the bilateral transfer of practice in tactual discrimination. It remained for William James to extend this procedure to the study of higher mental processes. James had come to doubt the popular belief that the faculty of remembering can be strengthened by exercise and decided to put his view to an experimental test (1890, I, pp. 666f.). He set out to determine whether prolonged practice in memorizing the poetry of one author would lead to increased efficiency in memorizing the poetry of another author. Equivalent selections from one poet were used in the pretest and the posttest, and verses of another poet were used during the intervening period of training. There was no evidence of transfer. The absence of transfer effects appeared to confirm James's view that the capacity for remembering—what he called general retentiveness—is a physiological trait not susceptible to training. Whatever increases in the proficiency of memory do occur must be attributed to "the improvement of one's habitual modes of recording facts" (p. 667).

James's experiment presaged the approach to the problem of ability training that was soon to come into general use. The training and the test tasks were assumed to sample the same general ability—if such an ability did, indeed, exist—but they differed in content, so that the specific habits which had to be mastered were not identical. Some of the methodological problems that had to be resolved in subsequent work are also apparent. Only differences between pretest and posttest were considered; changes in performance during the daily practice sessions were not measured. A failure to observe transfer to a new task is inconclusive as long as it is not known whether the training procedure had a direct effect. The equivalence of the pretest and the posttest was not established, and the need for a control treatment also remained to be recognized. The necessary changes in design and analysis were introduced gradually in the studies which followed.

Even when the training produces no apparent improvement, as in James's experiment, the lack of a control baseline may lead to incorrect conclusions. It is possible that the transfer effect from pretest to posttest is negative, in which case a zero difference indicates a positive influence of training. A much more probable source of error is, however, a failure to take account of the improvement attributable to the pretest when the experimental treatment is apparently effective. The well-known experiment by Ebert and Meumann (1905) is a case in point. In this study the training phase consisted of daily practice in the memorization of nonsense syllables. The

pretests and posttests comprised a variety of memory tasks; the materials to be recalled included letters, numbers, nonsense syllables, nonsense figures, words, German-Italian vocabulary, verses, and prose passages. After the pretest there were two eight-day periods of training, each followed by a posttest. The subjects showed considerable improvement in their ability to memorize nonsense syllables; in addition there were successive increases in performance on the posttests. Thus, the training activity appeared to have produced broad transfer effects. However, the lack of a control treatment proved to be a fatal shortcoming and subsequent work showed the conclusions to be invalid. Gains comparable to those in the original experiment were observed when the training was omitted and only the tests were administered at the appropriate intervals (Dearborn, 1909). In a repetition of the original experiment with a control group added, Reed (1917) again observed a striking improvement in the performance of the training task but found no consistent differences between the test scores of the experimental and the control group.

The inclusion of a control group became standard practice in studies of memory training, but the findings remained inconclusive at best. Winch (1908) reported an improvement in the memorization of prose after a period of training on poetry; in a subsequent study (1910) he also observed substantial gains from practice on letter series to the memorization of prose. It is not known, however, whether the pretest and posttest in these experiments were of equal difficulty. In a more extensive investigation Sleight (1911) for the first time introduced the precaution of counterbalancing pretests and posttests. In Sleight's main experiment the subjects were girl pupils whose average age was 12 years 8 months. On the basis of ten different pretests, which provided measures of both immediate memory and rote learning, the subjects were divided into four matched groups. Three groups were assigned to experimental treatments and were given practice in memorizing either poetry, tables of measures and other quantitative facts, or the substance of prose passages. There were two three-week cycles of practice (four 30-minute sessions per week), each followed by a posttest. The control activity consisted of work on arithmetic problems. There were gains on the posttests under all conditions. However, the net transfer effects on the final tests, as measured by the differences between the control and the experimental groups, were for the most part small and not significant; 14 of the 30 differences were negative. A further study with adults yielded similar results.

Sleight's study is free from the major methodological flaws that vitiated some of the earlier work: An appropriate control condition was included, the groups were well matched, and the pretest and posttest tasks were counterbalanced. One important shortcoming was the failure to obtain measures of performance during the training phase; it is probable, however, that the practice was effective. The results could reasonably be viewed as damaging to the hypothesis that any training in memorization produces broad transfer effects that facilitate the performance of any new and different memory task.

There are two inherent limitations in the formulation of the experiments designed to measure the spread of ability from a given amount of special memory practice. First, there was no systematic manipulation of the similarities and differences between the training and the test tasks; this is true for both the specific content of the material and the performance requirements at each of the stages of the experiment. The question at issue was, after all, how specific the effects of training are. There could be no answer to this question as long as dimensions of intertask similarity were not specified with sufficient precision to permit of experimental manipulation. In that respect the findings of Thorndike and Woodworth (1901) on transfer of training in observation and judgment were far more illuminating and theoretically significant. In some of their experi-

ments the subjects were trained in perceptual skills such as the estimation of rectangular areas. In the transfer tests the stimuli to be judged were varied systematically with respect to such characteristics as shape and size; in other experiments subjects had practice in canceling particular letters and then were tested with other letters or words. Transfer effects were typically small and irregular; that is, the benefits derived from practice were sharply reduced when the training and test stimuli were not identical even though they were drawn from the same general class.

A second pervasive shortcoming of the experiments on memory training was the failure to determine the limits of possible improvement in the performance of the transfer tasks even if training were successful. The test tasks were frequently activities with which the subjects undoubtedly had had considerable experience prior to the experiment, such as memorizing poetry or the substance of prose passages. If they had already reached a reasonable level of proficiency before embarking on their special training, there would be little opportunity for detecting an improvement. On the other hand, if the test task is novel and difficult, for example, the memorization of a list of nonsense syllables, the limited experience afforded by the pretest is likely to produce substantial improvement under both the experimental and the control treatment; consequently, the sensitivity of the posttest to the transfer effects of the intervening training is reduced.

The evidence remained consistent with James's dictum that "all improvement in memory consists . . . in the improvement of one's habitual methods of recording facts." The repeated failures to find broad transfer effects implied that the habits permitting the efficient performance of a given task were highly specific and unlikely to generalize to new situations. Such specificity may be entailed by differences in the requirements of successive tasks, but it may also be a consequence of the learner's failure to develop methods of practice that can be carried over from one assignment to the next. Both these factors may, of course, be responsible for the lack of transfer in any given case. However, as long as the subject is left to his own devices during the training phase, the potentialities for transfer through the development of widely applicable methods of practice remain unexplored. Thus, even when there are no gains under standard conditions of practice, appropriate guidance during the training phase may substantially increase the breadth and amount of transfer.

This possibility was examined in an experiment by Woodrow (1927). All subjects received pretests and posttests on six different memory tasks. The materials to be memorized included poetry, prose, factual information, Turkish-English vocabulary, and historical dates. The span of immediate memory for strings of consonants was also measured. During the four-week period intervening between the two tests the subjects were divided into three groups. A control group received no memory training. A "practice group" devoted two sessions per week to the memorization of poetry and of lists of nonsense syllables. The total amount of time spent on these exercises was approximately three hours. A "training group" followed the same schedule but divided its time between the memory tasks and instruction in efficient methods of memorizing. About 40 percent of the training time was given over to instruction. The techniques in which the subjects were trained included the following: "learning by wholes; use of active self-testing; use of grouping and rhythm; attention to meaning and use of images and symbols to embody meaning; mental alertness and concentration; confidence in one's ability to memorize; in certain cases, as in learning nonsense syllables, the use of secondary associations." On the posttest the difference in improvement between the practice and the control group was small and unreliable; the training group,

however, showed considerable gains and surpassed the other two groups by a substantial amount. It should be noted that under the control condition the intercorrelations among the various tests tended to be low, averaging .38, so that a rather broad transfer effect was demonstrated. The results leave open the question, however, whether it was the instruction alone, or the instruction in combination with the memory exercises, that was responsible for the superior performance of the training group. To answer this question, an additional group given the instruction but not the exercises would have been needed. In any event, Woodrow's findings call attention to the fact that in the classical studies of memory training the composition of successive tasks was emphasized at the expense of the methods which make for efficient performance.

While the early results concerning intertask transfer were variable and inconclusive, all the available evidence indicated that as long as the nature of the task remained the same, subjects would show progressive improvements in performance. The more unfamiliar and difficult the learning task, the more likely such practice effects were to be observed. Most of the subsequent studies of nonspecific transfer concentrated on the conditions and characteristics of the improvement in the performance of one particular type of task. Such progressive increases in speed of learning will obviously influence test-task performance in any transfer experiment in which the nature of the task remains unchanged. It is a curious fact, however, that the methodological implications of this state of affairs for the measurement of specific transfer effects were very slow to be recognized. As we pointed out in our discussion of experimental designs, specific transfer effects must be measured from a control baseline which permits an assessment of the nonspecific effects of prior training. Such control treatments have become a standard feature of transfer designs only in the relatively recent past; in the many experiments which failed to include these essential controls there was a systematic bias toward overestimating specific positive transfer effects and underestimating specific negative transfer effects.

NONSPECIFIC TRANSFER: WARM-UP AND LEARNING TO LEARN

Warm-up

A failure to observe associative interference where it would be expected on theoretical grounds first led to an explicit discussion of the need for separating net transfer effects into nonspecific and specific components. In 1928 Heron reported the results of an experiment in which he had intended to investigate the interference produced by the attachment of a new response to an old stimulus (*A–B, A–D*). In a given experimental session two lists of six pairs of nonsense syllables were learned in immediate succession. The second list had either zero, two, or four pairs in which the stimulus terms were the same as in the first list. In addition, there was a preliminary practice session. A counterbalanced design was used, and subjects served under all four treatments in sessions four weeks apart. The somewhat unexpected finding was that in each session the second list was learned faster than the first; that is, no absolute negative transfer effects were observed. There was, however, no improvement between sessions. Heron attributed the transitory within-session improvement to a process of "warming-up" akin to the "limbering up" in the performance of a motor skill. He viewed this process as distinct from the transfer of habits. Thus, the positive effects of warm-up served to counteract the associative interference during the acquisition of the second list but did not influence speed of learning in the session which followed four weeks later.

Definition of warm-up The assumption that warm-up is a source of improvement in verbal learning eventually gained wide acceptance. It is interesting to note, however,

that 20 years elapsed between the appearance of Heron's article and the initiation of studies of the characteristics of warm-up in rote learning. Interest in the problem was reactivated by Ammons' (1947) systematic analysis of warm-up effects in motor learning. In this analysis warm-up was identified with the establishment of the postural set required for the efficient performance of a motor task such as rotor pursuit. The set is assumed to dissipate gradually during rest intervals. The loss of set results in reduced efficiency of performance, designated as warm-up decrement. This conception of warm-up in terms of task set was found to be readily applicable to the rote-learning situation (Irion, 1948). The set comprises the postural and attentive adjustments that make for optimal reception of the verbal stimuli and modes of responding appropriate to the experimental arrangements, for example, the rhythm of the memory drum. The subject's adjustments also provide a feedback of response-produced stimulation which serves to maintain a distinctive situational context. In agreement with the principles established in the area of motor learning, the beneficial effects of warm-up on the performance of a subsequent task should be an increasing function of the amount of set-inducing practice and inversely related to the time interval between the two activities (McGeoch & Irion, 1952, p. 334).

Certain features and implications of this interpretation of warm-up deserve emphasis. First, warm-up is viewed as the establishment of a transitory set that prepares the subject for the perceptual and motor requirements of the experiment. The set is built up and maintained as long as the warm-up activity is continued but begins to dissipate as soon as that activity is terminated. Thus, transitoriness is a defining characteristic of warm-up effects. Second, to facilitate the subsequent performance of a learning task, the warm-up activity need not involve any learning; any activity that induces the appropriate postural and attentive adjustments should be effective. However, prior learning is obviously one such activity. When nonspecific transfer is observed from one learning task to the next, the question arises at once whether all of the facilitation is attributable to warm-up, or whether in addition efficient methods of learning were acquired as a result of the prior training. The latter would constitute learning to learn as distinct from warm-up. To distinguish between these two components of nonspecific transfer, the criterion of temporal persistence has been invoked. The logic of inference is as follows. By definition, there is a rapid dissipation of warm-up effects after the cessation of practice. On the other hand, the habits that constitute learning to learn are assumed to represent relatively permanent changes in behavior. Thus, nonspecific transfer effects that dissipate rapidly are attributable to warm-up, and those which persist over protracted intervals of time are evidence of learning to learn (Thune, 1951).

To validate these assumptions, it was necessary first of all to demonstrate that warm-up effects in rote learning have the characteristics attributed to them, namely, a cumulative build-up during the set-inducing activity and a progressive and rapid dissipation after the end of the activity. Two closely related experiments by Thune (1950) and Hamilton (1950) were directed at this objective.

The influence of warm-up on learning Thune's study comprised two experiments. The first of these was designed to test the hypothesis that the magnitude of the warm-up effect is an increasing function of the amount of prior set-inducing activity. Since interest centered on the determination of warm-up effects, an attempt was made to hold the opportunities for learning to learn constant and to minimize specific transfer by the use of unrelated lists. The experiment was carried out on two successive days. On Day 1 all subjects first received six trials on a practice list of 15 paired associates composed of one-syllable nouns. The second stage consisted of 10 trials on a list of 15 pairs of
Figure 21.1. Nonspecific transfer effects in acquisition. Performance on a paired-associate test list as a function of the number of immediately preceding trials on an unrelated practice list. (Thune, 1950.)

two-syllable adjectives (List A). The various groups in the experiment differed with respect to the distribution of these trials between Day 1 and Day 2. For one of the groups the distribution was 10–0; that is, all 10 trials were given on Day 1; other combinations were 8–2, 6–4, 4–6, 2–8, and 0–10. The final test task was administered on Day 2 and consisted of 10 trials on a list of 15 pairs of one-syllable nouns (List B). Practice on List B was preceded by a 10-minute rest interval during which the subjects sorted cartoons. Thus, all subjects had the same amount of experience with paired-associate learning but had varying numbers of trials on List A immediately before the beginning of the test trials on List B. Figure 21.1 shows the mean numbers of correct responses during the acquisition of List B as a function of the number of trials on List A completed just previously. Performance on the test task is related directly to the number of preceding practice trials. Thune attributed this relation to the progressive build-up of a warm-up effect during the trials on List A.

The second experiment in Thune's study evaluated the effectiveness of a nonlearning activity as a condition of warm-up. The activity chosen was color guessing which was carried out in a manner designed to simulate the experimental arrangements in paired-associate learning. Specifically, when a large capital *X* appeared in the window of the memory drum, the subject was required to guess which one of five colors would appear when the shutter lifted. The colors were presented in different random orders on successive trials. Two groups were compared. On Day 1 both groups received six practice trials of paired-associate learning and 10 trials on List A. The second stage consisted of 10 trials of color guessing, and as before the critical variable was the temporal locus of the warm-up activity: for one group these trials occurred on Day 1, and for the other on Day 2 just prior to the acquisition of list B. Performance on the test task was substantially better in the latter case. Perhaps even more important, comparison of corresponding groups in the two experiments showed that 10 trials of color guessing and 10 trials on List A immediately preceding the test task
Figure 21.2. Mean number of correct responses on the first 2 anticipation trials in the acquisition of a transfer list as a function of the degree of first-list learning. The successive lists conformed to the *A–B, A–D* paradigm. The dashed lines represent the performance of the control group which had no prior learning. (Underwood, 1949.)

produced equal amounts of improvement. This finding led Thune to conclude that regardless of whether or not the prior activity involved learning, the source of facilitation was the reinstatement of an appropriate perceptual-motor set. We shall return to this conclusion below.

The implication of Figure 21.1, that the amount of nonspecific transfer is a direct function of the number of prior practice trials, is confirmed by the results of other studies. As was suggested by Heron's results, the gains in performance may be sufficiently great to mask the presence of associative interference. A clear example appears in Figure 21.2. The data are from an experiment by Underwood (1949) in which the relation between degree of prior learning and proactive inhibition was investigated. The learning materials were lists of 10 paired adjectives which conformed to the *A-B, A-D* paradigm. First-list learning was carried to one of three criteria: 3/10, 8/10 or 10/10 plus 5 overlearning trials. The average numbers of trials to these criteria were 4, 11, and 20, respectively. The figure shows the mean numbers of correct responses on the first two anticipation trials of second-list learning as a function of the amount of practice on the first list. There are progressive gains in performance relative to the control group which received no prior training; the net transfer effect remains negative only at the lowest degree of prior learning and becomes increasingly positive thereafter. Relative to a control group learning two unrelated lists (*A-B, C-D*), negative transfer is found even at high degrees of first-list practice (Spiker, 1960; Jung, 1962; Postman, 1962a; Spence & Schulz, 1965).

Hamilton's study was designed to measure the speed with which warm-up effects dissipate. The general procedure and learning materials (Lists A and B) were the same as in Thune's experiment described earlier. All subjects received preliminary practice on Day 1, and on Day 2 learned Lists A and B. The time interval between the first and the second list was varied over a range from 8 seconds
Figure 21.3. The dissipation of warm-up. The decline in the mean number of correct anticipations reflects the effect on test-list learning of increases in the length of the interval since the end of practice on a prior list. (Hamilton, 1950.)

to 240 minutes. Figure 21.3 shows the relation between the length of the rest interval and the mean numbers of correct responses in test-list learning. As the interval is lengthened, performance declines rapidly at first and more slowly thereafter. Thus, the relation is adequately described by a negatively accelerated function.

Warm-up vs. learning to learn Taken together, the results of Thune and Hamilton indicate that both the build-up and the dissi-
Figure 21.4. Temporal trends in nonspecific transfer effects during continued practice. Three successive lists of paired associates were learned on each of 5 days. The large gains within sessions are to be contrasted with the relatively small gains between sessions. (Thune, 1951.)

pation of warm-up effects occur rapidly. In a subsequent study Thune (1951) presented further evidence for the apparent transitoriness of warm-up effects and attempted to assess the relative contribution of warm-up and learning to learn to cumulative gains in performance. The subjects in this experiment learned three lists of 10 paired adjectives each day for five days. Practice on each list was for 10 trials or to a criterion of one perfect recitation. Meaningful relations among the words in the successive lists were minimized as far as possible; that is, the paradigm of transfer was *A–B*, *C–D*, *E–F*, and so on. The mean numbers of correct responses on the first five anticipation trials for each of the three lists learned in the five successive sessions are shown in Figure 21.4. Two trends are at once apparent: the presence of very large gains within sessions and much smaller ones between sessions. The difference between the two improvement functions is well brought out by the fact that the first list on the fifth day was learned to criterion less rapidly than the second list on the first day. In principle, both warm-up and learning to learn may contribute to the gains observed on a given day. However, since warm-up effects are known to dissipate rapidly, Thune considered it likely that most of the within-session improvement was a matter of warm-up. The cumulative changes between sessions, on the other hand, provide an estimate of the temporal course of learning to learn. It appears that the gains attributed to learning to learn describe a negatively accelerated increasing function, and the magnitude of the warm-up effects appears to be largely independent of the level of practice. The fact that the within-session gains are greatest on the first day is attributed by Thune to the greater initial weight of the learning-to-learn component.

These conclusions are predicated on the assumption that the effects of learning to learn persist between successive days, whereas those of warm-up dissipate. There is empirical support for the latter supposition, although it is by no means certain that some of the adjustments subsumed under warm-up are not conditioned to the situation and hence carried over from one session to the next. The assumption that the habits that constitute learning to learn are not forgotten is ad hoc and open to question. In support of this assumption McGeoch and Irion (1952, p. 308) cite the finding of Bunch (1936) that transfer is highly resistant to forgetting, but the "rational learning problem" used in this study may well represent a special case. Consider on the other hand the results found in an experiment by Newton and Wickens (1956, Exp. II) in which two lists of paired adjectives (*A–B*, *C–D*) were learned either 0, 24, or 48 hours apart. The average number of trials to criterion on the first list was about 20. The mean numbers of trials required to master the second list to the same criterion were 10, 16, and 21 at the successively longer intervals. On the assumption that warm-up effects had fully dissipated, the trend indicates a progressive forgetting of learning to learn, which was complete after 48 hours. If the intervals between sessions in Thune's experiment had been 48 hours (or perhaps longer in view of the higher levels of practice), the estimates of learning to learn would most likely have been substantially smaller. In short, the identification of learning to learn with between-session improvement is questionable; consequently assessments of the differential effectiveness of warm-up and learning to learn on the basis of comparisons of within-session and between-session gains are of very uncertain validity.

The finding in Thune's earlier study that color guessing and list learning produced equal amounts of facilitation suggested that the rapid gains observed early in practice were largely a matter of warm-up. However, all of the subjects in that experiment had had prior experience with the learning procedure used in the terminal test task. It is possible, therefore, that the effects of the warm-up treatment were not independent of the prior learning experience. The color-guessing trials
Figure 21.5. The development of nonspecific transfer effects in naive subjects. Performance on a paired-associate test task after practice on either another learning task (*LT*) or a nonlearning task (*NLT*). Under each condition there were either 4 or 10 training trials. The control group had no prior practice. (Schwenn & Postman, 1967.)

may have been effective in producing facilitation not so much because they reinstated the subject's perceptual-motor set but because they served to reactivate habits acquired during the previous verbal practice. To compare the effectiveness of a learning and a nonlearning activity in the initial stage of practice it is necessary to use naive subjects.

Such a comparison was made in a study by Schwenn and Postman (1967). The test task was the acquisition of a list of paired adjectives. The prior activity consisted either of learning a list of unrelated pairs of adjectives (*A–B, C–D*) or of number guessing under conditions simulating as closely as possible the experimental arrangements in the learning situation. There were either four or ten trials of prior practice. A control group was not given any preliminary training. Performance on the common test task is shown in Figure 21.5. At both levels of practice there is a substantially greater gain after a learning than after a nonlearning activity. Four trials of number guessing had no effect whatever, whereas the same number of learning trials was sufficient to produce a significant amount of improvement. There is a small but consistent gain after 10 guessing trials, but the differential effectiveness of the two treatments remains clearly in evidence at the higher level of practice. Since both activities would presumably be conducive to the development of an appropriate perceptual-motor set, it follows that the rapid improvement in performance typically shown by naive subjects reflects primarily the acquisition of skills relevant to the requirements of a learning task per se.

These results do not necessarily call into question the importance of perceptual and motor adjustments, especially under the conditions of rapid pacing, which are characteristic of rote-learning situations. However, there may be important differences between the adjustments required by a learning and a nonlearning task. In learning a list, the subject must spend some of the available time in rehearsal, in searching for mnemonic devices, and in editing his responses. The demands on the subject's time are not the same during the performance of, say, a guessing task. Consequently, the optimal distribution of attention and most efficient rhythm of responding are probably far from identical in the two situations. In fact, modes of responding appropriate in a "pure" warm-up task may make for errors in a subsequent learning situation. For example, the color-naming procedure often used in studies of distributed practice to fill the intertrial intervals has been shown to increase the probability of overt errors because the set to respond to every stimulus is carried over into the learning trials (Underwood, 1952). Along similar lines, it was observed in the study of Schwenn and Postman that relative to the control condition the rate of overt errors was higher after number-guessing but lower after list-learning. It is true that error rate and speed of learning are not necessarily correlated (Scheible & Underwood, 1954). Nevertheless the possibility cannot be ruled out that a warm-up activity may, under certain circumstances, become a source of interference as well as of facilitation. Thus, a sharp separation between per-

ceptual-motor adjustments and the development of efficient methods of learning may not be psychologically valid. In any event, the studies of Thune and of Schwenn and Postman taken together point to an interaction between stage of practice and warm-up effects. In a naive subject preliminary training on a set-inducing task produces little facilitation; when the subject is experienced, a few trials on such a task may reinstate the complex of adjustments and habits that make for efficient learning.

Warm-up and retention Interest centers explicitly on the effects of the reinstatement of an appropriate performance set when the influence of warm-up on retention is considered. One basic approach to this problem was developed in the analysis of motor-skill performance (Ammons, 1947). In skill learning the concept of warm-up decrement refers to a loss of set during a rest interval which produces a transitory decline in performance. The presence of a warm-up decrement is indicated by the fact that the initial segment of the relearning curve after rest has a steeper slope than the original acquisition curve at a comparable level of initial proficiency (Irion, 1948). The relearning curve is steeper because of the rapid reinstatement of set when practice is resumed. If the entire decline in performance represented "true" forgetting, the learning and relearning curves at comparable levels should have the same slope. When the amount retained is measured on a recall trial, the role of warm-up decrement in forgetting can be assessed by the introduction of a set-reinstating activity immediately prior to the retention test proper. The gain in recall produced by the warm-up activity provides an estimate of the extent to which a loss of set contributes to the total amount of forgetting. The amount of gain should be related directly to the degree of continuity between the warm-up and learning tasks.

A study by Irion (1949) provided impressive support for the hypothesis that warm-up decrement is a major determinant of retention loss. In a first experiment a list of 15 paired adjectives was learned for 10 trials and then relearned for 10 trials after varying intervals ranging from 1 minute to 24 hours. A no-rest control group received 20 successive acquisition trials. The amount recalled on the first relearning trial was a negatively accelerated decreasing function of the length of the retention interval. As predicted, the slope of the relearning curve, at least after a 24-hour interval, was steeper than that of the original learning curve at the same level of initial proficiency. In Irion's second experiment it was found that a warm-up trial of color naming just prior to the start of relearning eliminated most of the forgetting after a 24-hour interval. In fact, the subjects given a delayed test after warm-up did not differ significantly from the no-rest control. In a subsequent study (Irion & Wham, 1951), in which serial lists of nonsense syllables were the learning materials, a rest interval of 35 minutes was used and the amount of warm-up was varied systematically. The recall scores showed an upward trend as a function of increasing amounts of warm-up, although the relation was rather irregular. It is noteworthy that after four trials of warm-up, recall was significantly higher than under the no-rest control condition.

Irion's results suggested that a loss of set may account for much of the forgetting normally observed on delayed tests of retention. This conclusion would, of course, have important implications for forgetting theory. Unfortunately, however, it has proved impossible to replicate the original finding reported in Irion's (1949) study, namely, that retention losses after 24 hours are drastically reduced by having subjects engage in a warm-up activity before the test of recall. Complete failure of an attempt at replication was reported by Rockway and Duncan (1952) in spite of concerted efforts to duplicate the conditions of the original experiment as closely as possible. These investigators also failed to find an effect on retention of the amount of warm-up activity; the similarity

between the warm-up and the learning task with respect to length and rate of responding likewise had no reliable influence on performance. Later Dinner and Duncan (1959) found a significant increase in recall after warm-up, but only when the degree of original learning was substantially higher than in the earlier experiments. Recently Lazar (1967) carried out a series of experiments in which the conditions of warm-up prior to recall were varied in a number of different ways but with almost entirely negative results. The reasons for the striking discrepancy between the results of Irion and those of subsequent investigators are unclear. It is apparent by now, however, that the reduction in retention loss by a set-reinstating activity is not a dependable phenomenon.

The concept of warm-up and the phenomena presumably associated with it pose some serious interpretative difficulties, at least as far as verbal learning and memory are concerned. One major problem, to which reference was made earlier, is the definition of an appropriate perceptual-motor set which is independent of the element of learning. The assumption that an activity such as color naming or number guessing establishes such a set may in some cases be wholly or partially erroneous, and there is a risk that sources of negative as well as positive transfer may be disregarded. A second problem concerns the interaction of warm-up effects with stage of practice. As we have seen, there are reasons to believe that a warm-up activity influences the behavior of naive and experienced subjects differentially, perhaps because there is a change in the function which it serves. Finally, the problem of separating out the relative contribution of warm-up and learning to learn to the improvement observed within a given learning session has not been fully solved.

Conditions and Characteristics of Learning to Learn

We now turn to a consideration of experiments concerned primarily with learning to learn, that is, the acquisition of learning skills
Figure 21.6. Progressive improvement in the acquisition of serial lists of nonsense syllables. Each list consisted of 12 items. The mean numbers of trials to a criterion of one perfect recitation are plotted for the successive lists. (Ward, 1937.)

as a result of practice. The conditions of these experiments make it possible in most cases to set aside the problem of the relative weight of warm-up and learning to learn. In many cases the successive practice sessions were spaced sufficiently far apart to justify the assumption that strictly transitory warm-up effects had fully dissipated between one task and the next; improvements in performance may then be seen as the retention of learned skills. In other cases the primary interest is in comparisons of different conditions of practice, with warm-up effects assumed to be held constant.

Serial and paired-associate learning There are typically substantial increases in speed of acquisition when lists of the same type are learned in succession. Figure 21.6 shows the progressive changes in rate of learning observed in an experiment by Ward (1937) in which subjects learned 16 successive serial lists of nonsense syllables. The sixteenth list required less than half as many trials to criterion as the first list. The magnitude of the practice effects is especially noteworthy in view of the fact that there inevitably is considerable duplication of letters among lists of nonsense syllables. Consequently there is a build-up of formal interlist similarity and
Figure 21.7. Speed of paired-associate learning as a function of stage of practice. Each list was carried to a criterion of 8 out of 10 responses correct. (Greenberg & Underwood, 1950.)

hence of sources of associative interference. Nevertheless the numbers of trials to criterion decline steadily. The function has the characteristic negatively accelerated form, but the limits of improvement for this type of task were probably not reached. For example, Melton and von Lackum (1941) reported that subjects who had had 28 days of previous practice in learning nonsense syllables, words, and numbers still showed improvement in an experiment in which the materials were lists of consonant syllables. It is likely that the period of continued improvement varies directly with the difficulty of the materials; thus, practice effects appear to level off quite rapidly in serial learning when the lists are composed of English words (Postman, 1962c).

Figure 21.7 shows changes in the speed of acquisition of lists of paired adjectives (Greenberg & Underwood, 1950). Successive sessions were spaced either 24 or 72 hours apart; learning on each list was carried to a criterion of 8/10. There was a substantial amount of improvement, but virtually all of it occurred in a single session. When a higher criterion is used, such as one perfect recitation, improvement in this type of task is more gradual and extends over a large number of sessions (Warr, 1964; Keppel, Postman, & Zavortink, 1968). Nevertheless the contrast between Figures 21.6 and 21.7 supports the conclusion that the speed with which the practice curve reaches asymptote is inversely related to the difficulty of the task. The magnitudes of the gains are difficult to compare in view of the differential opportunities for improvement.

A detailed description of the changes in performance that reflect learning to learn has been given by Duncan (1960). A nonverbal paired-associate task was used, with visual forms as stimuli and lever movements as responses; it is likely that the major quantitative trends apply to verbal lists as well. There were 10 sessions distributed over two five-day weeks. A different task was practiced for 20 trials on each day. The basic conclusions regarding the progressive changes in performance may be summarized as a series of points. (1) As usual, overall performance increased as a negatively accelerated increasing function of the number of preceding sessions. (2) Learning to learn had its greatest effect fairly early during the practice on a given task, namely, during the second fifth of the learning period. The ceiling of performance limits the possibilities of improvement. (3) Consequently the learning curves will show progressively steeper slopes even when the asymptote is not affected. (4) As learning to learn continues, the stability of correct responses increases; that is, it becomes less and less likely that the first occurrence of a correct response will be followed by an error. (5) Initially slow learners register considerably greater gains than do initially fast learners. Such a difference is to be expected whenever the opportunities for detecting improvements are limited by an asymptote. It cannot, therefore, be inferred that the benefits of practice are greater for slow than for fast learners in an absolute sense. The analysis brings into focus the sensitivity of indices of learning to learn to the opportunities for improvement at a given point in practice.

Conditions of learning to learn Once learning to learn has been demonstrated, the question arises of what the habits and skills are that are responsible for the progressive improvements in performance. The designa-

tion of transfer as nonspecific clearly does not answer this question and conceptually does not advance very far beyond the historical assumption that some kind of ability has been strengthened. While the changes in performance cannot be attributed to the carrying over of specific discriminations or responses from one task to the next, they must nevertheless be assumed to reflect circumscribed habits and skills that depend on the conditions of prior practice and are applicable to a limited range of new situations. One approach to the identification of the components of nonspecific transfer is the comparison of conditions of practice which may be assumed to foster different kinds of skills. A few studies bearing on the analysis of improvement in paired-associate and serial learning will illustrate this line of investigation.

It is known that the efficiency of performance on a given task is an increasing function of the amount of prior practice on similar tasks. Is the progressive improvement attributable to the amount of practice per se or to the experience with a variety of tasks afforded by continuing practice? To the extent that the latter factor can be shown to be significant, it follows that one of the skills which is developed is the application of effective methods of practice to different tasks of the same type. In an experiment directed at this question Duncan (1958) used the nonverbal paired-associate task described earlier. The number of training tasks and the amount of practice were manipulated in an orthogonal design. Different groups received training on either 1, 2, 5, or 10 tasks. The amount of training was manipulated by giving 2, 5, or 10 days of practice at the rate of 20 trials per day. All groups were tested on two common final tasks. Improvement was found to be a direct function of both the total amount of practice and the degree of variation in training, with no interaction between these variables. Thus, varied training produced greater effects than constant training when the amount of practice was held constant; with degree of variation held constant, transfer increased with the amount of practice. Duncan suggests that experience with a variety of tasks renders the subject increasingly sensitive to the relevant dimensions of the stimulus terms. He may learn "as a general, transferable principle, that it is of value to look carefully at each stimulus presented, not only to its obvious characteristics, but also to any minor details" (1958, p. 71).

An analysis of the conditions and characteristics of learning to learn must inevitably return to the question which was at issue in the early studies of memory training: How specific is nonspecific transfer, that is, how wide is the spread of improvement from training on a particular task? To answer this question it is necessary to vary systematically the similarity relations between training and test tasks. In this context similarity refers, of course, not to particular stimulus or response elements but rather to the nature of the requirements that must be met by the learner. Thus, one may inquire to what extent the habits and skills that constitute learning to learn are peculiar to the method of practice and the class of materials used in the training phase. The specificity of learning to learn with respect to these task characteristics was investigated in an experiment by Postman and Schwartz (1964). There were four conditions of training that represented the factorial combination of two methods of practice and two classes of materials. The method used in the training phase was either serial or paired-associate learning, and the materials were either trigrams or familiar adjectives. There were two test tasks: a serial list of adjectives or a paired-associate list of adjectives. For each test task there were two groups, therefore, for which the method of practice in training and test remained the same and two groups for which it changed. Similarly, there were two groups for which the class of materials was kept constant and two groups for which it changed. There was no prior training under the control treatment. The acquisition curves for the paired-associate
Figure 21.8. Mean numbers of trials to successive criteria on a list of paired adjectives after different conditions of prior training. The preceding list was learned by either the paired-associate (PA) or the serial (S) method and consisted of either adjectives (A) or trigrams (T). The control group had no prior training. (Postman & Schwartz, 1964.)

test list are shown in Figure 21.8. While all conditions of training produced increases in speed of learning, the gains were significantly greater when the method of practice remained the same than when it changed; that is, subjects with prior experience in paired-associate learning were superior to those shifted from a serial to a paired-associate task. The findings are parallel for class of materials but the effects are less pronounced. Differences among the conditions of training were less important when the test task was serial. The nature of the prior training did appear to influence the subjects' mode of attack on the serial task; for example, there was evidence that experience with paired-associate learning disposed the subjects to subdivide the series into a sequence of pairs. However, variations in speed of learning were minor, apparently because the different modes of attack fostered by the prior training proved to be equally effective. The results of the experiment support three general conclusions: (1) There is sufficient communality between the habits established by serial and by paired-associate training for substantial improvement to occur under all conditions; the same holds for the acquisition of meaningful and of nonsense material. (2) The differences among treatments reflect components of learning to learn specific to method of practice and class of materials (see Postman, Keppel, & Zacks, 1968). The differential transfer effects evident in Figure 21.8 appear relatively late in practice and may be attributed to increases in relevant associative skills. (3) When a task such as serial learning can be approached in alternative, and equally effective ways, more than one appropriate condition of prior training may produce equivalent amounts of gain but for different reasons. Thus, there may be systematic transfer effects that are not revealed by measures of speed of learning.

Free-recall learning The distinguishing characteristic of free-recall learning is that the subject is permitted to reproduce the items in the list in any order he wishes, that is, without regard to the order of input. The score on a test of free recall is, therefore, determined by the sheer number of items reproduced. When multiple trials are given on the same list, progressive improvements in performance have been shown to be related to the subjects' tendency to group individual items into higher-order units (Tulving, 1962, 1968). Hence, increased skill in the formation of higher-order units is a potentially important source of nonspecific transfer.

Evidence concerning nonspecific transfer in free-recall learning has been accumulating slowly, and there are still some apparent inconsistencies in the existing data. Progressive improvements are in general not as great as in the classical rote-learning situations, and the amount of nonspecific transfer is more sensitive to variations in the conditions of practice. An early study showing very substantial practice effects in free-recall learning was reported by Meyer and Miles (1953). The materials were lists of 12 nonsense syllables which were presented for five study-recall cycles. For a given list the order of presentation was fixed but recall was free.

The "method of retained members" was used, that is, subjects were given 30 seconds on each trial to study the entire list and then 30 seconds for free recall. One list was learned under these conditions in each of 20 successive sessions. The amount recalled increased as a negatively accelerated function of the number of prior sessions. The overall mean score rose from 24 to 34 between the first and the twentieth session. While these are impressive transfer effects, it must be recognized that the conditions of this study differ in important respects from those characteristic of most experiments on free-recall learning. First of all, the learning materials were nonsense syllables. A major part of the subjects' effort had, therefore, to be devoted to the integration of the items per se. Thus, much of the improvement may have been due to increases in response-learning skills. Unless there is an explicit concern with response learning, words are typically used in studies of free recall because of the emphasis on such factors as the subjective organization of items and the relation between input and output order. Thus, the use of the method of retained members, with presentation of nonsense syllables in a fixed serial order, represents an experimental arrangement that is not readily generalized to other studies of free recall.

A well-known study by Murdock (1960) also used rather special conditions, in this case with respect to test-trial procedures. The materials were lists of 30 common English words which were presented for four study-test cycles. On the test trials subjects were presented with a list of the initial letters of the items and were required to complete the words. In one experiment there were five sessions spaced at one-week intervals during each of which a single list was learned; in another experiment six successive lists were learned in one session. In neither case was there any evidence for nonspecific transfer. There are reasons to believe that the conditions of testing served to minimize the opportunities for improvement. The use of alphabetized blanks may have discouraged subjective organization of items according to their meaning (see Tulving, McNulty, & Ozier, 1965, p. 251). As will be shown shortly, improved effectiveness of subjective organization is one of the factors making for improvement in free recall. Moreover, because of the inevitable overlap in initial letters an *A–B, A–D* relation obtained for at least some of the cues and responses in the successive lists, which is known to be conducive to interference (Zavortink & Keppel, 1968).

More recent studies have produced clear evidence for nonspecific transfer in free-recall learning but have also served to delimit the conditions under which it may be expected to occur. In an experiment by Dallett (1963) practice effects within a single session extending over 10–15 lists were investigated for ordered as well as for free recall. (Under conditions of ordered recall the sequence of items in presentation is kept constant, and subjects are required to reproduce the list in the correct serial order.) An important variable manipulated in this study was the frequency of test trials. In Dallett's first experiment 10-item lists were presented one, three, or five times before the first and only test of recall; in the second experiment there were 10 cycles consisting of a study and a test trial for each list. There was evidence for learning to learn for ordered recall in both experiments, but for free recall only when multiple test trials were given. Analysis of serial-position curves indicated that one source of improvement in ordered recall is a shift in the distribution of effort from the beginning of the series to the list as a whole, and particularly to the terminal items that have the benefit of recency in recall. These changes in learning strategy appear to develop in the absence of interspersed test trials. Where recall is free, it is likely that the subjects' ability to organize the list into higher-order units is significantly aided by interspersed tests. The fact that speed of free-recall learning and degree of subjective organization increase concurrently as a function of practice was demonstrated in a study

by Tulving, McNulty, and Ozier (1965) in which three successive lists were presented for eight study-recall cycles each within a single session. This conclusion also receives support from a recent experiment by Mayhew (1967) in which the design paralleled that of Thune's (1951) study of within-session and between-session changes.

In Mayhew's experiment each subject learned six 30-word lists, two per day for three consecutive days. Each list was presented for 10 study-recall cycles. Half the subjects were given standard free-recall instructions, whereas the other half were given information about potentially useful ways of organizing the words in a list. The learning scores and the indices of subjective organization (Tulving, 1962) showed parallel trends, which were not unlike those reported by Thune: substantial increases within sessions but much smaller gains between sessions. The indices of subjective organization were higher and increased at a faster rate for the instructed than for the standard group, and the differences in recall were in the same direction. It is interesting to note that the indices of subjective organization as well as the recall scores show rapid rises within sessions followed by a decline from one day to the next. It would not be reasonable to consider degree of subjective organization a matter of warm-up; nevertheless the temporal trends are those conventionally identified with warm-up effects. Thus, these findings help to reinforce the question raised earlier about the criterion of temporal persistence used to differentiate between warm-up and learning to learn.

SPECIFIC TRANSFER: SIMILARITY RELATIONS

Stimulus-Response Analysis

Transfer effects are designated as specific when they are attributable to known similarity relations between the components of successive tasks. The similarity relations are critical because they determine what responses and dispositions are carried over from one situation to the next. If the laws of specific transfer are to be determined experimentally, it is necessary to identify the relevant components of the successive tasks and to vary them systematically. The usefulness of a stimulus-response analysis for this purpose was demonstrated in an early study by Poffenberger (1915), whose procedures represented a transition between the conventional design used in studies of ability training and the method of successive practice. In one investigation the experimental group was given protracted training in naming the opposite of each of 50 adjectives, for example, *broad-narrow*. In the pretest and the posttest both the experimental and the control group were instructed to give an appropriate noun to each of the same adjectives, for example, *street* or *shoe* to *narrow*. The expected negative transfer effect was observed. In another phase of the study the experimental subjects were practiced in canceling particular numbers and were tested on either the same or different numbers. A positive transfer effect was found when the numbers remained the same but none when they changed. On the basis of his findings Poffenberger proposed three generalizations: transfer effects are (1) positive when both the stimulus and the response remain the same, (2) negative when the stimulus remains the same and the response changes, and (3) zero when both the stimulus and the response change. In terms of current notation, the three paradigms are: *A–B, A–B*—positive; *A–B, A–D*—negative; *A–B, C–D*—zero. A short time later Wylie (1919) added a fourth principle, namely that the transfer effects are positive when the stimulus changes and the response remains the same (*A–B, C–B*). Evidence for the latter principle was obtained in a study of maze learning with rats in which the animals were successively trained to make the same response to different signals such as lights and sounds.

These principles were subjected to a comprehensive test in a study of paired-associate transfer by Bruce (1933). He used lists of

TABLE 21.2

	Trials of List-1 Learning			
Paradigm	0	2	6	12
A–B, C–D (IX)[a]	9.9	9.9	10.7	8.3
A–B, A′–B (VIII)	13.5	11.4	8.7	5.9
A–B, C–B (V)	14.4	16.6	12.0	9.0
A–B, A–B′ (IV)	9.6	9.8	9.7	7.7
A–B, A–D (I)	10.3	12.1	11.9	11.2

[a]The number of the condition in the original article is given in parentheses.

paired nonsense syllables as learning materials. The number of trials on the first list was either 0, 2, 6, or 12; the second list was learned to a criterion of one perfect recitation. There were nine paradigms of transfer defined by the similarity relations among the stimulus and the response terms in the two lists. The lists were not balanced; thus a different test list was used under each condition of transfer. The subjects assigned to a given paradigm were tested at all four degrees of first-list learning. This was repeated for four cycles, with one list learned per day. Of the nine paradigms of transfer we will consider only five, which represent the basic conditions of interlist similarity; in the remaining cases intrapair and interlist similarity were varied concomitantly, and it is difficult to separate the relative contributions of these two factors. Table 21.2 lists the five paradigms of interest in current alphabetical notation. Similar stimuli are designated as *A* and *A′*, similar responses as *B* and *B′*. In this experiment, such items have the first two letters in common but different third letters. The entries in the table are the mean numbers of trials to criterion on the second list.

The scores obtained without prior learning suggest that not all transfer lists were of equal difficulty. Ability differences among the groups ($N = 9$) may have been a contributing factor. (In previous discussions of this experiment the transfer results have usually been presented in terms of percentages to the base of trials to mastery without prior learning. However, in view of the apparent differences among test lists the percentages may be somewhat misleading.) Precise evaluation of at least some of the differences among paradigms is, therefore, difficult. A reasonably unbiased comparison can be made only between the *C–D* condition on the one hand, and the *A–B′* and *A–D* paradigms on the other. In general, the results appear to show the expected pattern: There is evidence of negative transfer for *A–D,* and of positive effects increasing with the degree of List-1 learning when the responses are the same or similar. To the extent that the proposed principles were confirmed, they were shown to hold for degrees of similarity other than identity. Attention was also focused on the importance of the level of first-list learning as a determinant of transfer. The study is certainly of historical importance as an early systematic investigation of the paradigms of transfer. From the vantage point of present-day methodology it is not a satisfactory experiment because different test lists were used under the various treatments. The resulting problems of interpretation have already become obvious. This difficulty applies to many studies of transfer in the literature, since the use of a common test list has become standard practice only in the fairly recent past.

Generalization and Transfer

Gradients of transfer When degrees of stimulus similarity short of identity are considered, the continuity between the operations used to measure transfer and the generalization of conditioned responses becomes apparent. In both cases the question is asked

whether and to what extent a response associated with a training stimulus is elicited by more or less similar test stimuli. Stimulus generalization is typically measured by means of tests of performance (somewhat analogous to posttests), whereas the method of successive practice is the characteristic procedure for assessing transfer. Recognition of the continuity between these two classes of operations was important because the principles of stimulus generalization proved to be a significant tool in the theoretical analysis of transfer. For this reason some historical importance attaches to the early transition experiments, which were designed to demonstrate stimulus generalization in associative learning. A classical study by Yum (1931) is a case in point.

In Yum's first experiment the learning materials were lists of 14 paired associates, with two hyphenated nonsense syllables as the stimulus terms and English words as responses. The list was learned to a criterion of one perfect recitation, and a test of generalization was given 24 hours later. There were seven types of test stimuli represented by two items each. One condition of testing consisted of the presentation of the original syllables; in the other cases either the first letter, the second letter, or both were changed in one of the syllables. With three types of alterations for each of the two syllables, there were six kinds of generalization stimuli. Significantly fewer correct responses were given to all the altered stimuli than to the original ones. A change in the first letter of either syllable was more damaging than a change in the second letter; in fact the alteration of two letters produced only slightly poorer performance than alteration of only the first. The results show a generalization decrement at recall and at the same time indicate that the effective similarity between the training and the test stimulus depends critically on the locus of the change. The latter finding is consistent with the evidence subsequently obtained in studies of stimulus selection; that is, the first letter of a trigram is more likely to become a functional stimulus than the middle one (Jenkins, 1963a; Postman & Greenbloom, 1967).

In the second experiment lists of 12 paired words were learned. The stimuli used on the delayed test were either the original words or words rated as having one of two degrees of meaningful similarity to the items in the list. Pronounced generalization decrements were again observed. In the third experiment the learning materials were lists of 15 pairs, in which visual nonsense forms were the stimuli and English words the responses. There were five types of test stimuli: original figures and figures having four rated degrees of similarity to the original ones. The percentage recalled was a negatively accelerated decreasing function of the degree of similarity between the training and the test stimulus. Comparable findings were reported by Gulliksen (1932) and McKinney (1933).

Studies such as Yum's served to exhibit the continuity between the measurement of stimulus generalization and of associative transfer. As will become apparent shortly, subsequent theoretical analysis of verbal transfer leaned heavily on the assumption that verbal stimuli generalize along dimensions of both meaningful and formal similarity. It is useful to note at this point that there has been substantial independent confirmation of this assumption. One important line of evidence comes from experiments showing semantic generalization of conditioned responses. When the conditioned stimulus is a word, the level of generalization of the conditioned response varies with the degree of similarity or of associative connection between the conditioned and the test stimulus (for example, Razran, 1939, 1949; Mednick, 1957). Conditioned responses have also been shown to generalize along a dimension of formal similarity defined, much as it was by Yum, in terms of the number of altered letters (Abbott & Price, 1964). Mention should also be made here of studies investigating mediated generalization of instrumental responses, such as a lever press. In these experiments the

relation between the training and the test stimuli is one of associative linkage (Mink, 1963) or similarity of connotative meaning (Dicken, 1961). It is by no means certain that the mechanisms responsible for the generalization of conditioned or instrumental responses to verbal stimuli and for similarity effects in verbal transfer are the same (for a review of theoretical interpretations of semantic conditioning see Maltzman, 1968). The results of the conditioning experiments do, however, constitute independent empirical evidence of generalization among verbal stimuli.

Tests of generalization are usually administered after the end of practice. A variation on this procedure was recently introduced by Jenkins and his collaborators (Jenkins & Brown, 1965; Brown, Jenkins, & Lavik, 1966). The basic feature of the technique is the use of interspersed tests of generalization during the later stages of practice on a learning task. In one experiment (Brown et al., 1966), a list of nine paired associates composed of English words as stimuli and nonsense syllables as responses was learned for 10 trials. On trials 11 through 19, four of the nine stimuli presented to the subject were new, whereas the remaining five were from the original list. The subject was instructed to guess what the responses to the new stimuli might be; there was no feedback after the guesses. The new test stimuli had either a zero, low, intermediate, or high normative probability of being given as a response to the original stimulus in free association. The number of transfer responses increased progressively as a function of the degree of associative connection between the original and the test stimulus. In another experiment (Jenkins & Brown, 1965) the same test procedure showed that generalization is greater when the original and the test stimuli are associatively rather than semantically related (see Ryan, 1960). This finding was confirmed by Kasschau and Pollio (1967) who used separate lists for each type of response relation.

A gradient of generalization has also been reported for the recognition of verbal items, with degree of similarity again defined in terms of the number of changed letters (Postman, 1951). The experimental arrangements for the measurement of recognition and of associative learning are, of course, quite different, so that extrapolations from one process to the other must be made with considerable caution. Recent evidence suggests, however, that recognition of the stimulus term may be an essential condition for the elicitation of associative responses (Bernbach, 1967; Martin, 1967a, b). It is possible, therefore, that generalization of recognition plays a part in associative transfer.

Gibson's hypothesis A systematic application of the complementary concepts of generalization and differentiation to verbal learning, and to transfer and interference in particular, was formulated by Gibson (1940) in an influential paper. Gibson's analysis takes its point of departure from the proposition that generalization occurs among verbal stimuli and that the reduction of generalization (differentiation) is an essential condition of learning. Generalization is exemplified in the paired-associate situation when a response learned to one stimulus is elicited by other stimuli as well. If the list is to be mastered, generalization must be reduced by differential reinforcement. That is, the correct responses must be reinforced and the generalized responses not reinforced. (In the verbal-learning situation presentations of the correct responses presumably create the necessary conditions of reinforcement.) The greater the initial degree of generalization the more reinforced practice is required for differentiation to be established and the more difficult the learning task becomes. After the end of practice differentiation dissipates over time, that is, generalization tendencies show spontaneous recovery, just as do extinguished conditioned responses. The more differential reinforcement has been given during acquisition the more slowly spontaneous recovery will occur.

Before the extension of this analysis to transfer and interference is considered, it will be useful to make explicit certain inherent limitations of the theory and to examine the experimental operations that were used to test it. Most of the points to which attention will be called were considered in detail in an evaluation of Gibson's theory by Underwood (1961).

1. The degree of generalization that obtains among a particular group of stimuli is specified on an entirely empirical basis. "A *generalization gradient* is said to be formed when a number of stimulus items show decreasing degrees of generalization with a standard stimulus. The hypothesis need make no assumption as to the type of stimulus continuum which will yield a generalization gradient" (p. 204). Gibson adds, however, that it is consistent with the hypothesis to suppose that stimuli arranged along a scale of similarity will yield such a gradient; hence the degrees of interitem similarity and of generalization would normally be expected to be correlated. The decision to specify gradients of generalization in purely empirical terms led to experimental operations that tended to blur somewhat the distinction between independent and dependent variables in tests of the theory.

Figure 21.9. Examples of nonsense figures used by Gibson as stimulus terms in paired-associate lists. The similar and the less similar figures define two different degrees of generalization with respect to the standard. (Gibson, 1941.)

The stimuli used by Gibson were nonsense forms (Figure 21.9). To obtain sets of stimuli that could be ordered with respect to degree of generalization Gibson (1941) used the following procedure. Each of a series of standard forms was given a nonsense name, and the subjects had five study-test cycles on these paired associates. On the following day a test list was presented that contained some of the standard forms, variants judged to represent two different degrees of similarity to the standards, and some entirely unrelated forms. The subjects were instructed to write down the appropriate name of the form whenever they could. The percentages of recall were 85, 41, and 10 for standard, similar and less-similar forms, respectively. There were less than 3 percent attempts to respond to the unrelated forms. The results of this normative procedure were then used to define three degrees of interstimulus generalization for subsequent experiments. This method of specifying a theoretically anchored independent variable is relatively weak because essentially the same effects are measured in the normative situation and in the experiments in which the norms are applied: the probability that a variant will elicit a response associated with the standard. Thus Gibson (1942) found that high-generalization lists, in which both standards and their variants appeared as stimuli, were learned more slowly and yielded higher error frequencies than low-generalization lists composed of standards only. The learning experiment can be seen as a validation of the results of the normative test, and the same holds true for some of the findings on transfer to be discussed later. That is not the same, however, as a prediction of differences in learning and transfer on the basis of independently scaled stimulus characteristics. To be sure, judgments of similarity were
obtained by Gibson in the development of her figures, but the point at issue concerns the method used to *scale* the degree of generalization for the purpose of predicting learning and retention. A predictor variable determined by operations quite independent of behavior in a learning situation is much to be preferred.

2. As Underwood points out, the emphasis in the development of the hypothesis is on sensory generalization, just as it was in Pavlovian conditioning. Within this framework there is a disposition to view generalization as the mechanism responsible for the effects of nonsensory as well as of sensory characteristics of stimuli. Thus meaningfulness is conceptualized by Gibson in terms of interitem discriminability. Specifically, it is assumed that the degree of interitem generalization is inversely related to meaningfulness. It is on this basis that speed of learning is predicted to increase with stimulus meaningfulness. As it turned out, the influence of meaningfulness on speed of acquisition is at best moderate when this factor is varied on the stimulus side in a paired-associate list, as compared with the powerful effects on the response side (Underwood & Schulz, 1960). There is little in the available evidence that points to degree of interitem generalization as the variable underlying the relation between meaningfulness and learning. In short, discriminability is stressed at the expense of other potentially critical properties of verbal items.

3. The theory fails to consider the effects of response generalization. There was no strong evidence for the importance of this mechanism at the time when Gibson's position was formulated. As will be seen shortly, the significant role of response similarity, notably in transfer and interference, was not long in being established.

These limitations have to be borne in mind when the applications of the theory to the problems of transfer and interference are considered. (It must be recognized, of course, that the criticisms are made largely from the vantage point of information based on more recent developments. There is little question but that Gibson's theory made an important contribution in opening up new avenues of analytic experimentation.)

Stimulus generalization and transfer Gibson's point of departure in the analysis of transfer and interference is the assumption that stimulus generalization occurs not only within lists but also between lists. When there is generalization between the stimulus terms in two successive lists, the first-list responses will be elicited during second-list learning. The higher the degree of generalization, the greater will be the magnitude of the resulting transfer effects. The direction of transfer will depend on whether the responses in the two lists are the same or different. If the responses remain the same, the effects will be positive because the generalizing and the correct responses coincide. If the responses change, the effects will be negative because the generalizing and the correct responses are in conflict. Parallel predictions are made for recall of the first list, that is, for retroactive facilitation and interference and on the same basis, but for the present only the evidence on transfer will be considered.

The data most directly relevant to these predictions come from experiments in which Gibson's visual forms were used as the stimulus terms. Complementary experiments by Hamilton (1943) and Gibson (1941) investigated the cases of positive and negative transfer, respectively. The stimulus items and the procedure in the two studies were identical, except that the same responses were used in the two successive lists in Hamilton's study and different responses in Gibson's. Each list consisted of 12 paired associates with visual forms (Figure 21.9) as stimuli and nonsense syllables as responses. In the first list the standard forms were the stimuli. There were four conditions of second-list learning distinguished by the characteristics of the stimuli: the forms in the second list were either the same as those in the first or rep-
Figure 21.10. Transfer as a function of degree of interlist stimulus generalization. Mean trials to a criterion of 8/12 on the transfer list are plotted. In Gibson's experiment the response syllables in the first and in the second list were different; in Hamilton's experiment they were the same. (Data from Gibson, 1941; and Hamilton, 1943.)

resented first-degree, second-degree, or zero-degree generalization between the successive stimuli. Both lists were learned to a criterion of 8/12. The conditions in Hamilton's experiment may be denoted as *A–B, A–B; A–B, A′–B; A–B, A″–B;* and *A–B, C–B.* The corresponding groups in Gibson's experiment are: *A–B, A–D; A–B, A′–D; A–B, A″–D; A–B, C–D.* Speed of List-1 learning was quite similar in the two experiments, so that a direct comparison of the transfer results is in order. The mean numbers of trials to criterion on the second list are shown in Figure 21.10. It will be noted, first of all, that second-list learning is much faster when the responses remain the same than when they change. This difference is undoubtedly attributable to the transfer of response learning (availability of the nonsense-syllable responses) in the former case.

There is only limited evidence for the predicted relation between degree of stimulus generalization and amount of transfer. Moreover, the shape of the gradient is quite different in the two experiments. All that can be said is that the amount of transfer diminishes as one moves from identical to similar and then to unrelated stimuli. This relation is less pronounced when the effects are positive than when they are negative. The two degrees of generalization (*A′* and *A″*) differ but little from each other. Since the case of stimulus identity does not appear to be admitted by Gibson as a case of maximal generalization (see Underwood, 1961, p. 201), the prediction is only weakly supported. If the *C–D* condition in Gibson's experiment is considered as the control baseline, there is negative transfer for all groups with changed responses and positive transfer for all groups with identical responses. The results for the corresponding conditions obtained in a subsequent study by Bugelski and Cadwallader (1956) show a gradient for the positive, but not for the negative, paradigms.

All three studies share the limitation that a different second list was used under each of the conditions, so that precise comparisons of the amounts of transfer are not possible. A more recent experiment by Dallett (1962a), in which Gibson's forms were again used as stimuli and English words as responses, did use a common second list. The two 12-pair lists were learned for 7 trials each. The mean numbers of correct responses in second-list learning were as follows:

A–B	—[a]	*A–D*	47.4
A′–B	61.2	*A′–D*	45.6
A″–B	62.7	*A″–D*	51.5
C–B	48.7	*C–D*	52.0

[a]Not included in this study.

There is positive transfer relative to the *C–D* control baseline when the stimuli are similar and the responses remain the same (but note that the effect is negative when the stimuli are unrelated). However, there is no differ-

ence between the two degrees of stimulus similarity. When the responses are new, the transfer effects are negative, and the expected difference between the two degrees of similarity is found. However, *A″–D* and *C–D* are equal. The predicted regular transfer gradients once more failed to materialize. Again all that can be concluded is that the amount of transfer is some increasing function of stimulus similarity.

Changes in transfer as a function of similarity have also been investigated with English words as the stimulus terms. One common definition of similarity is in terms of synonymity (Haagen, 1949). Using lists of eight paired adjectives as the learning materials, Staner (1956) compared the amounts of transfer obtained under conditions of high, medium, and low stimulus similarity when the responses in the successive lists remained identical. As expected, the amount of transfer increased directly with stimulus similarity. A pattern consistent with Staner's results may be found in a study by Wimer (1964), but the latter failed to find corresponding effects when responses were unrelated, that is, for negative transfer.

The degree of relation between stimulus (or response) words has also been scaled in terms of the strength of the associative connection between them. When the stimulus words in successive lists are associatively related, transfer is greater than when they are unrelated. Thus, Ryan (1960) found that after the acquisition of *A–B,* positive transfer effects were greater for the *A′–B* than *C–B* paradigm. In general, then, the amount of transfer is an increasing function of the degree of meaningful similarity or associative connection between the stimulus words in successive lists.

Response generalization in transfer Gibson's theory was basically incomplete because it failed to consider the role of response generalization along with that of stimulus generalization. The importance of relating transfer to both types of generalization was brought into focus in a series of experimental and theoretical contributions by Osgood (1946, 1948, 1949, 1953). The argument for response generalization is made with reference to the meaningful similarity of words. Each word is assumed to evoke a "meaning reaction" or mediating response (r_m). The mediating response produces internal stimulation (s_m), which can function as a cue for overt responses such as the emission of the appropriate word. As a result of reinforced practice, say on a paired-associate task, there is a growth in the excitatory tendency for the stimulus to evoke the meaning reaction characteristic of the prescribed response. At the same time an inhibitory tendency is built up for the stimulus not to evoke the exactly opposite meaning reaction. Excitatory and inhibitory increments summate algebraically. The probability of overt emission of the prescribed response word varies directly with the net strength of the appropriate excitatory tendency. Both the excitatory and inhibitory tendencies are assumed to generalize, with generalization occurring among r_ms and s_ms. The assumption of complementary tendencies of excitation and inhibition, which are built up concurrently by reinforced practice, introduces a feature not found in conven-
Figure 21.11. Hypothetical gradients of response generalization in paired-associate learning, showing spread of excitatory and inhibitory tendencies. For a full explanation see text. (Osgood, 1946.)

tional analysis of mediated generalization (Hull, 1943).

The implications for transfer become apparent when we consider the gradients of excitation and inhibition that are assumed to exist at the end of first-list learning. A picture of the theoretical situation is shown in Figure 21.11. Consider a list in which the stimuli are bigrams and the responses are adjectives. One of the pairs is *cm-elated.* This association has been built up during the learning trials. The excitatory tendency will generalize to similar meaning reactions, for example, *high,* but not dissimilar ones, for example, *left.* In addition, there is an inhibitory tendency for the stimulus not to evoke the directly opposite reaction, in this case *dejected.* This tendency will in turn generalize to responses which lie on the gradient for *dejected,* such as *low.* The latter is described by Osgood as an "opposed," as distinguished from an opposite or "antagonistic," reaction. The transfer effects in second-list learning will vary with the position the new response occupies on one or the other of the generalization gradients. The analysis can be extended readily to predict variations in retroactive inhibition since the generalization of excitatory tendencies developed during interpolated learning will add to the strength of the original association, and generalization of inhibitory tendencies will subtract from it.

The predictions derived from this analysis were tested by Osgood in two experiments. Both were studies of retroactive interference, but for the present only the transfer data will be considered in detail. In the first experiment (1946) the learning materials were lists of 15 paired associates, with bigrams as stimuli and adjectives as responses. The responses in the second list were either similar, unrelated, or opposed in meaning to those in the first list. Each similarity relation was represented by five responses in the second list. (The use of a mixed list is favored by Osgood because it prevents the establishment of a systematic response set.) Each pair in the first list was learned to a criterion of one correct anticipation, whereas the pairs in the second list were carried to two correct repetitions. The lists were so balanced that each pair represented the three similarity relations equally often. A measure weighted for speed of responding was used to assess performance on the transfer list. Similar pairs were learned better than either unrelated or opposed ones; the latter did not differ. In the second experiment (1948) the lists consisted of 14 paired associates constructed as before. The responses of half the pairs were similar in the two lists; the other half were opposed (but not antonyms). The pairs in the first list were learned to a criterion of one perfect anticipation; the second list was learned for either 1, 2, 4, or 8 trials. The transfer performance of all the groups was evaluated on the first trial. There was no reliable difference in the number of correct responses between the two types of pairs, but response latencies were shorter when the responses were similar than when they were opposed. In both experiments the variations in amount of retroactive interference parallel the findings for transfer. In general, the support for the hypothesis is not impressive. The observed effects of response similarity are not large and are limited to latency measures or indices of performance weighted for speed of responding. There is no evidence of a regular gradient of response generalization.

Osgood's transfer surface Leaning heavily on the data obtained by Gibson and Hamilton, and in his own studies, Osgood (1949) formulated the following empirical laws of transfer and retroaction:

1. Where stimuli are varied and responses are functionally identical, positive transfer and retroactive facilitation are obtained, the magnitude of both increasing as the similarity between the stimulus members increases. This law is supported by Hamilton's (1943) results.

2. Where stimuli are functionally identical and responses are varied, negative transfer and retroactive interference are obtained, the magnitude of both decreasing as similarity
Figure 21.12. Osgood's transfer and retroaction surface. (Osgood, 1949.)

between the responses increases. The paradigms ranging from *A–B, A–B′* to *A–B, A–D* are encompassed here; the relevant evidence is a composite of the findings of Gibson (1941) and Osgood (1946, 1948). Note that negative transfer is expected to decrease as responses become more similar but that the law stops short of predicting positive transfer.

A third law is added which is designed to account for the fact that in studies of serial learning negative transfer and interference increase with the degree of similarity between successive lists (McGeoch & McDonald, 1931; Johnson, 1933; McGeoch & McGeoch, 1936; Melton & Von Lackum, 1941). The formulation of this law is based on the assumption that in a serial list each item serves as both a stimulus and a response.

3. When both stimulus and response members are simultaneously varied, negative transfer and retroactive interference are obtained, the magnitude of both increasing as stimulus similarity increases.

The three laws are integrated in the well-known transfer and retroaction surface (Osgood, 1949) which is reproduced in Figure 21.12. The vertical dimension represents the direction and amount of transfer or retroaction. Degrees of stimulus similarity ranging from neutrality (unrelated items) to identity are spaced along the width of the solid. Degrees of response similarity, which vary from identity to antagonism, are distributed along the length of the solid. The median horizontal plane represents zero transfer or retroaction. When the stimuli in successive tasks are unrelated, all points fall on the median plane of the surface. For other degrees of stimulus similarity zero effects are expected at some point between response identity and response similarity. Thus, the occurrence of greater than zero transfer is shown to depend on the presence of some degree of stimulus similarity; the direction of transfer depends on response similarity. However, as the sharply inflected function on the front edge of the surface indicates, positive effects are predicted only for identical or nearly identical responses.

The surface represented an important systematic attempt at an integration of the total range of transfer and interference phenomena. However, it is fair to say that the surface was erected on a rather shaky empirical foundation even when the data available at that time are considered.

The most important empirical weakness was the lack of clear evidence for the orderly transfer gradients which are a central feature of the model. For stimulus similarity the data of Gibson and Hamilton, on which Osgood placed heavy reliance, give only limited support to theoretical expectations. As for response similarity, Osgood's own data contain some evidence for the positive influence of this variable but in no way confirm the extension of the gradient to opposed and antagonistic responses. No difference between unrelated and opposed responses was found; antonyms were not included in the lists. The transfer effects for opposed and antonymous responses are likely to be complexly determined because differences in meaning may be offset by associative connections.

Two other uncertain assumptions incorporated in the surface should be noted. The first of these is that as long as the stimuli are unrelated, transfer effects will remain at zero, regardless of the similarity relation between

responses (back edge of surface). The empirical basis for this principle was provided by the combined data of Gibson and Hamilton (see Figure 21.10). However, there were indications in Bruce's (1933) results that a difference in favor of the paradigm of response identity (*A–B, C–B*) may emerge at higher degrees of first-list learning. Subsequent work has supported the conclusion that significant transfer effects occur for this paradigm, with the amount and direction of transfer determined by both the meaningfulness of the responses and the degree of first-list learning. The second assumption which proved questionable concerns the one-to-one correspondence between variations in transfer and retroaction. Such congruence was to be expected on theoretical grounds and in general was found in the available data. There was, however, an important exception in the results of one of Gibson's studies which gave an early indication that the functions for transfer and retroaction are not necessarily identical. The conditions in that experiment were the same as those depicted in Figure 21.10 except that there was also a control group which learned and recalled a single list (Gibson, 1941, Exp. I). Relative to the control group the *A–B, C–D* paradigm (unrelated stimuli and unrelated responses), which defines the condition of zero transfer, yielded a substantial amount of retroactive inhibition. We shall encounter other cases in which the correlation between transfer and retroaction does not hold.

Other surfaces The similarity relations depicted in Osgood's surface apply to individual pairs in the successive lists. The influence of list structure cannot be taken into account. Consequently, the surface cannot generate accurate predictions for what later turned out to be a powerful paradigm of negative transfer, namely, the re-pairing of the first-list stimuli and responses in the second list (*A–B, A–Br*). Within the framework of the surface, this paradigm reduces to *A–B, A–D* since the stimuli remain identical and the second-list response to each individual stimulus is new. However, as originally predicted by Gagné, Baker, and Foster (1950), re-pairing maximizes negative transfer and produces greater effects than the attachment of new responses to old stimuli. For paired-associate verbal learning the differential effectiveness of the *A–Br* and *A–D* paradigms in producing negative transfer effects was demonstrated by Porter and Duncan (1953), Besch and Reynolds (1958), and numerous other investigators thereafter. The stimuli and responses in the successive lists that are re-paired need not be identical but may be more or less similar to each other, for example, *A–B, A′–B′r; A–B, A″–B″r;* and so on. A surface representing the effects of stimulus and of response similarity for such noncorresponding pairings has been constructed by Dallett (1965). The surface complements Osgood's for corresponding pairings. However, for the points from the two surfaces sampled in Dallett's experiment the results are not complementary: variations in both stimulus and response similarity influenced the transfer effects for Osgood's paradigms, whereas only stimulus similarity had an effect in the re-paired conditions.

Even when only individual pairs are considered, Osgood's surface does not exhaust all the similarity relations between the members of the pairs in the successive lists. The stimuli in the first list (S_1) may be more or less similar to the responses in the second list (R_2), and so also for first-list responses (R_1) and second-list stimuli (S_2). To represent the effects of these similarity relations on transfer, Houston (1964a) relabeled Osgood's surface, substituting S_2–R_1 for stimulus similarity, and S_1–R_2 for response similarity. It follows from the geometry of the surface that the amount of transfer is predicted to be zero as long as S_2 and R_1 are unrelated. As these two terms become more similar, the amount of transfer increases, reaching its maximum when S_2 and R_1 are identical. The direction of transfer is determined by the relation between S_1 and R_2, being maximally negative when they are unrelated and maximally positive when they are identical (*A–B, B–D* and *A–B, B–A*, respec-

tively). Differences in transfer effects in accord with the predictions were later reported by Houston (1966a, 1966b). However, as Thompson (1966) has pointed out, the Osgood and Houston surfaces are incompatible and make divergent predictions for numerous paradigms. Perhaps the most telling objection to Houston's surface mentioned by Thompson is that it entails the prediction that learning will not take place. The paradigm for continued practice is *A–B, A–B,* in which S_2 and R_1 are unrelated, which according to the model means zero transfer effects from one trial to the next. On the other hand, Osgood's surface implies zero transfer for *A–B, B–A,* which is known to produce substantial positive effects (Murdock, 1956) as predicted by the other model.

One surface appears to lead to another. After the appearance of Dallett's (1965) surface for conditions of re-pairing, Houston (1965) developed one representing the re-paired versions of his own paradigms. It was predicted that negative transfer would increase as S_2 and R_1 become more similar; this increase should be greater when S_1–R_2 similarity is high than when it is low. The re-paired version encounters the same difficulties as the original one; for example, it appears to predict minimal negative transfer for the basic *A–B, A–Br* paradigm itself, since S_2 and R_1 are unrelated! A subsequent experimental test failed to yield the expected differences among re-paired paradigms (Houston & Morony, 1966).

The fact that a surface such as Houston's (1964a) has some apparent empirical validity but at the same time entails the absurd implication that learning cannot occur points up a basic weakness of such models. The source of the difficulty is that total transfer is related to two single dimensions of variation such as stimulus or response similarity. Both of the dimensions may well represent significant independent variables, but between them they determine only some of the component processes on which transfer depends. As a consequence some of the predictions fail, and important paradigms reflecting the contributions of other components cannot be accommodated. Thus, Osgood's surface applies to the transfer of forward associations, such as *A–B, A–D*. The *A–Br* paradigm cannot be handled because additional sources of transfer become critical—certainly backward associations and probably list differentiation. An examination of the paradigms on Houston's surface indicates that the operative factor is the relation between the forward associations in one list and the backward associations in the other, as illustrated by the contrast between *A–B, B–A* (maximally positive) and *A–B, B–D* (maximally negative). Surfaces are convenient representational devices, but any given model will be descriptive of some but not all of the *components* of transfer. The analytic usefulness of component surfaces will be illustrated shortly.

Response similarity: parasitic reinforcement or mediation? Regardless of the ultimate validity of the surface, Osgood's analysis made a major contribution in focusing attention on response similarity as a determinant of transfer. The particular scale of response similarity represented in the surface has not received much empirical confirmation. Tests of the total surface were carried out in the studies of Bugelski and Cadwallader (1956) and Wimer (1964) mentioned earlier. The former used identical, similar, neutral, and opposed responses; the latter included antonymous responses as well. In neither case was the predicted gradient of increasingly negative transfer effects obtained. In Dallett's (1962a) study, in which only identical, similar, and unrelated responses were used, the results conformed reasonably well to the predictions of the Osgood surface.

When only the range from response identity to neutrality is considered, there is substantial other evidence that as responses become more similar, the acquisition of the transfer list is increasingly facilitated (Morgan & Underwood, 1950; Underwood, 1951; Young, 1955; Staner, 1956). The assumption that response generalization is the

mechanism responsible for the gradient of facilitation (Osgood, 1946) was also formulated as the hypothesis of parasitic reinforcement (Morgan & Underwood, 1950). According to this interpretation reinforced practice on *A–B* during first-list learning not only strengthens the connection between *A* and *B*, but also between *A* and a range of responses similar to *B*. These generalized associations—*A–B′*, *A–B″*, and so on—receive parasitic reinforcement during the acquisition of *A–B*. The gradient of response generalization indexes the effects of parasitic reinforcement. To the extent that parasitic reinforcement has occurred, the List-2 associations are prelearned and require correspondingly less new learning.

One important implication of this hypothesis is that at a given level of response similarity the amount of positive transfer should be an increasing function of degree of first-list learning. This prediction follows from the assumption that direct and generalized associative strength vary together. Moreover, the higher the response similarity, the greater should be the gains in transfer produced by increases in degree of first-list learning. These expectations were fully confirmed in an experiment by Underwood (1951). The learning materials were lists of 12 paired adjectives. The degree of synonymity between the responses in the two lists was either high, medium, or low (zero). There were three criteria of first-list learning—4/12 correct responses, 7/12, or two successive errorless trials. The mean numbers of trials required to learn the second list to a criterion of 7/12 are shown in Figure 21.13. When the responses are unrelated, degree of first-list learning does not influence transfer. As degree of response similarity increases, the effects become substantial. This conclusion was strongly supported by the results of an item analysis. The relation was determined between the number of times the response to a given stimulus was reinforced during List-1 learning and the probability of a correct response to the same stimulus on the first transfer trial. The greater the response similarity, the more marked the positive relation was found to be. A further finding, which has been confirmed repeatedly, was that the frequency of intrusions from the first list during the acquisition of the transfer list increased with the degree of response similarity. Intrusions may be expected to occur when the responses from the two lists are of approximately equal strength, and this condition is most likely to develop when the level of generalization is high.

Figure 21.13. Mean numbers of trials to a criterion of 7/12 on the transfer list as a function of interlist response similarity and degree of first-list learning. *L, M,* and *H* refer to low, medium, and high response similarity, respectively. (Underwood, 1951.)

While many of the observed effects of response similarity are consistent with the hypothesis of parasitic reinforcement, there is strong support for an alternative interpretation, namely, that these effects are the result of mediation. Consider the *A–B, A–B′* paradigm, where there is a high degree of similarity between *B* and *B′*. Meaningful similarity and associative relation tend to be highly correlated (Haagen, 1949). It is possible, therefore, that after acquisition of *A–B*, activation of the associative chain *A–B–B′* will permit the subject to make the correct response in the transfer stage. There are several lines of evidence that suggest that such mediational chaining is in fact the effective mechanism of facilitation. (1) When the responses are synonymous, the amount of facilitation observed under optimal conditions of testing has been found to be extremely high. For

example, in a study by Barnes and Underwood (1959) an unpaced test of recall showed that list *A–B′* was learned almost perfectly in a single trial. As the investigators point out, one-trial transfer would indicate that there is essentially no gradient between *B* and *B′*. Thus, it becomes difficult to attribute the positive transfer effects to response generalization. On the other hand, an unpaced test would presumably maximize the opportunity for mediation and thus permit a very high level of performance. (2) In the same study nearly all the subjects reported that they had, indeed, used the first-list responses as mediators in learning the second list. (3) When the manipulated relation between *B* and *B′* is defined in terms of the degree of associative connection, for example, when the responses in the second list are normative primaries of those in the first although not necessarily synonymous, very substantial amounts of positive transfer are obtained (Bastian, 1961; Postman & Stark, 1964). In the latter study the characteristics of transfer performance were shown to parallel those observed with synonymous responses (Underwood, 1951).

Recently the mediation hypothesis has encountered a potentially serious difficulty. On the reasonable assumption that mediation takes time, mediational effects should increase as the response interval is lengthened. That is, the more time the subject has to give the required response in the transfer stage, the greater should be the likelihood of the mediational chain being successfully completed. The expected relation between the length of the response interval and amount of mediated transfer has, however, failed to materialize in several experiments. When the *C–D*, *A–D*, and *A–B′* paradigms were compared, there were no differential effects of changes in the duration of the response interval. The durations used in a study by Spear, Mikulka, and Podd (1966) were 1, 2, and 4 seconds; in an experiment by Richardson (1967c) they were .75, 1.5, and 3 seconds. Increases in the length of the interval serve to improve performance but do so about equally for all paradigms. Response time (1, 2, or 4 seconds) also failed to influence the amount of transfer in a study by Schwenn and Underwood (1965) in which the associative connection between the responses in the two lists was built in experimentally through prior paired-associate training. It is possible to ask whether the reductions in response time were perhaps not great enough to preclude mediation. Independent determinations of the latencies of implicit verbal responses (Richardson, 1967b, 1968b) indicate, however, that such is probably not the case.

An alternative explanation was recently proposed by Richardson (1968b) who did obtain the expected relation between the length of the response interval and amount of positive transfer when the study interval was shorter than in the other studies, that is, 1 second rather than 2 seconds. Given a sufficiently long study interval, the control as well as the experimental subjects have an opportunity to develop mediational links between the stimulus and the response; consequently both benefit from increases in the length of the response interval. However, when the study interval is very short, mediators are much more available to the experimental subjects who therefore derive a greater advantage from increases in the response interval. Implicit in the analysis is the recognition of the fact that mediated transfer depends on both the discovery and the utilization of the appropriate associative links (Schulz & Lovelace, 1964). Discovery is most likely to take place during the study intervals; utilization must occur during the response intervals. The amount of time available for both processes, under the control as well as the experimental treatment, must be taken into account. Richardson's hypothesis does not, however, explain positive transfer effects obtained with response intervals that are presumably too short to allow any mediation to occur. In accounting for such findings, the hypothesis of response generalization appears to have an advantage.
Figure 21.14. Component surfaces for response availability (*R*), forward associations (*F*), and backward associations (*B*). Degree of stimulus similarity is spaced along the X_S axis, and degree of response similarity along the X_R axis. The point of origin represents identity of both the stimulus and the response. Direction and degree of transfer are indicated along the vertical axis. (Martin, 1965.)

Components of Transfer

As became apparent in our discussion of surfaces, it is not possible to conceive of transfer effects as unitary because multiple processes come into play during the acquisition of both the training and the test list. Depending on the similarity relations between successive tasks, different sources of transfer become effective and influence the component processes of learning in the test stage to varying degrees. When there is more than one source of transfer, the magnitude and direction of their effects on performance may not only be different but may indeed be in opposition to each other. In the analysis of the components of transfer it has proved useful to specify what is carried over from the training to the test phase with reference to the distinction between response learning and associative learning.

According to this two-stage conception of acquisition (Underwood & Schulz, 1960, p. 92), the prescribed responses must become available before they enter into new associations. Thus, the subject who has mastered the first list carries over to the transfer task the results of both response learning and associative learning. The next step is to determine how these component habits influence second-list learning, again within the framework of a two-stage analysis (Postman, 1962a; Martin, 1965). Nonspecific transfer effects may influence both stages of acquisition and are assumed to be present for all paradigms. The locus, magnitude, and direction of the specific effects, on the other hand, depend on the conditions of intertask similarity. These have been conceptualized by Martin (1965) in the form of three component surfaces, which are reproduced in Figure 21.14.

The first of these represents the influence of response learning (*R*). The positive transfer effects decline progressively from a maximum to zero as the relation between the successive responses changes from identity to dissimilarity. The weight carried by this component of transfer is independent of the degree of stimulus similarity. The other two surfaces depict the conditions of associative transfer. The influence of forward and of backward associations is considered separately. Except for a change in the scale of response similarity, the surface for forward associations (*F*) is the same as Osgood's. Martin suggests that the scale position of opposite responses should reflect the degree of associative connection between them, and on this basis they would be located above, rather than below, entirely unrelated responses. For forward associations we find, as before, that the amount of transfer is an increasing function of the degree of stimulus similarity and that there is

a shift from positive to negative effects as the relation between responses changes from identity to neutrality. The coincidence of this surface and Osgood's brings home the fact that the latter represents only one component of transfer, namely, that attributable to forward associations.

Backward associations must be considered as an additional component because it is known that practice on *A–B* results in the development of the association *B–A* and that the latter can be a significant source of transfer. (For a review of the literature on backward associations see Ekstrand, 1966.) The *B* surface in Figure 21.14 shows the expected variation in transfer effects as determined by the relation between first-list and second-list backward associations under the various paradigms. The *B* surface is symmetrical in form to the *F* surface, so that the amount of transfer increases as a function of the degree of similarity between the response terms, ranging from maximally positive for *A–B, A–B* (backward associations *B–A, B–A*) to maximally negative for *A–B, C–B* (*B–A, B–C*). It should be noted that only relations between congruent associations are represented, that is, successive forward ones and successive backward ones.

These three components do not, of course, exhaust all the sources of specific transfer that can be postulated on theoretical grounds. In particular, the transfer of stimulus and of response differentiation from one list to the next (predifferentiation) may be added. Mastery of the first list requires discrimination among the stimulus terms and among the response terms. If the same or similar items are encountered in the second list, the prior establishment of the necessary discriminations may be expected to facilitate performance. Gibson (1940) suggested that predifferentiation is a positive factor when the stimuli in the two lists remain identical and the responses change, even though the net transfer effect is negative because of the opposing influence of associative interference. Saltz (1961) has argued that predifferentiation of the responses may likewise be a source of facilitation. It is his contention, for example, that the positive effects of prior response familiarization on paired-associate learning (for example, Underwood, Runquist, & Schulz, 1959) are to be attributed to the predifferentiation rather than the increased availability of the response terms. Thus, both types of differentiation deserve consideration in principle as potential components of transfer. To these a third type should be added, namely, list differentiation.

One possible source of error during the acquisition of a transfer list is the failure to identify the list membership of a pair correctly. For example, in learning *A–D* after *A–B*, the subject may know both the responses but give *B* instead of *D* because of a confusion between the two lists; such an error would be classified as an interlist intrusion. Alternatively, he may withhold *D* because he incorrectly identified it as a first-list response. It is reasonable to suppose that accuracy of list differentiation will vary inversely with the similarity of both stimulus and response terms; changes in either class of items provide the learner with distinctive cues to list membership. As the name implies, the differentia-

TABLE 21.3

Component	*Paradigm*				
	C–D	A–B′	A–D	C–B	A–Br
Response learning	0	(+)	0	+	+
Response differentiation	0	(+)	0	+	+
Stimulus differentiation	0	(+)	+	0	+
Forward associations	0	(+)	–	0	–
Backward associations	0	(+)	0	–	–
List differentiation	++	–(–)	–+	+–	––

tion here is between the lists as a whole rather than between the members of individual pairs. However, since the similarity relations between stimuli and between responses are assumed to be critical, list differentiation may be appropriately included among the components of specific transfer.

The Standard Paradigms of Specific Transfer

Recent experimental analyses of transfer have been largely limited to five basic paradigms: *A–B, C–D; A–B, A–B′; A–B, A–D; A–B, C–B; A–B, A–Br.* The reasons for the choice of these paradigms should by now be apparent; they represent conditions that may be expected to maximize the operation of various components and mechanisms of transfer, with *C–D* providing the control baseline for the effects of warm-up and learning to learn.

Table 21.3 identifies for each of the standard paradigms the component processes that are assumed to come into operation during the acquisition of the transfer task (for other such summaries see Martin, 1965, p. 339; Underwood, 1966, p. 525). A plus sign indicates a positive, and a minus sign a negative, effect. There are two entries for list differentiation: the first refers to the expected consequences of stimulus relations and the second to those of response relations. A zero entry means that the given component does not apply. For purposes of this tabulation it is assumed that the *A–B, A–B′* paradigm represents a high degree of synonymity or associative connection between responses. However, the effects of various components are taken not to be as great as they are in the case of response identity and they are therefore listed in parentheses.

A–B, C–D Table 21.3 makes it apparent why the *C–D* paradigm has become the standard control condition for the evaluation of specific transfer effects. The amount of warm-up and learning to learn may be reasonably supposed to be the same as for the other paradigms. The specific components are not applicable because both stimuli and responses are new, but the present table points to the possibility of an important exception: Precisely because all items in the first task are entirely dissimilar from those in the second, list differentiation is maximal. To the extent that failures of list differentiation can influence transfer performance, the control condition has a distinct advantage. Two other reservations regarding the validity of the *C–D* control baseline must be expressed. First, complete dissimilarity of both the stimulus and the response terms in the two lists is an essential defining property of this condition, but it may be difficult to meet this requirement in practice. In fact, when nonsense syllables are used as stimuli or responses, the requirement is bound to be violated because of the limited pool of letter elements. Nevertheless such materials continue to be used in experiments in which the appropriate implementation of the *C–D* paradigm is of critical importance for the interpretation of the results (e.g., Dean & Kausler, 1964; Houston, 1967b; Slamecka, 1967). In such cases severe biases in the interpretation of transfer and interference effects are likely to result. Second, it is in the nature of the *C–D* condition that during the acquisition of the successive lists the subject is exposed to a larger number of items than under any of the other standard paradigms. Thus, there is an inevitable bias against the control condition with respect to the amount of material learned; moreover, as the total pool of different verbal units is increased, it becomes more and more difficult to avoid uncontrolled interitem similarities both within and between lists. It must be concluded that the *C–D* paradigm represents at best an approximation to a control condition that is free of specific transfer effects. Absolute measures of specific transfer taken with respect to this baseline are, therefore, of uncertain validity for all types of materials, and certainly highly suspect when nonsense items are used. The use of this control remains nevertheless essential because of the need to take account of nonspecific transfer effects; clearly, however, it must be evaluated with considerable caution.

A-B, A-B′ Given a high degree of similarity or associative connection between the responses, all the entries in Table 21.3 are positive, with the exception of list differentiation. The latter is seen as difficult because of the identity of the stimuli and near identity of the responses. The characteristic course of transfer under this paradigm appears to bear out this assessment of the component processes. Transfer effects in the early stages of second-list learning are typically positive, especially when responses are associatively related but tend to become negative as practice on the test list continues (Postman, 1964a; Keppel & Postman, 1966; Postman & Stark, 1969). As was noted earlier, the frequency of interlist intrusions is relatively high; moreover, the intrusions are often persistent and their number is likely to increase during the early learning trials. These trends are consistent with the assumption that the positive effects are counteracted by failures of list differentiation which manifest themselves in generalization errors or confusions between mediators and mediated terms.

Within the framework of a mediational interpretation, the designation of the various components as positive rests on the assumption that the process of mediational chaining continues to operate throughout the course of transfer learning. To the extent that mediators are not used or drop out, *A-B′* reduces to *A-D*. The fact that the *A-B′* paradigm typically yields some retroactive inhibition, even under unpaced conditions (Barnes & Underwood, 1959; Postman, 1962b; Zavortink & Keppel, 1968), indicates that the *A-B′* and *A-D* paradigms may, indeed, shade into each other.

A-B, A-D This is the classical paradigm of negative transfer, with forward associations as the source of interference. Some of the early evidence for negative transfer in this condition has already been discussed. Recent studies have in general yielded the same result (for example, Twedt & Underwood, 1959; Postman, 1962a). There are growing indications, however, that the amount of negative transfer may be a function of meaningfulness. Using adjectives as stimuli and trigrams as responses, Jung (1963) found a relatively small amount of negative transfer when the meaningfulness of the response terms was low but a substantial effect when it was high (see Merikle, 1968). In an experiment by Goulet (1965), in which the learning materials likewise were adjective-syllable pairs, the meaningfulness of the first-list and second-list response terms was varied factorially. Negative transfer effects were greater when the meaningfulness of the first-list responses was high than when it was low. The results also indicated that a change in the meaningfulness of the responses served to reduce negative transfer, presumably by facilitating list differentiation. Other things being equal, high meaningfulness of the first-list responses favors the development of associations that can interfere effectively with second-list learning. A study by Richardson and Brown (1966), in which trigrams were used as stimuli and words as responses, shows that negative transfer also increases with the degree of stimulus meaningfulness.

Stimulus differentiation is a potential source of positive transfer whenever the stimuli in the successive lists remain identical. We shall not consider the investigations of pre-differentiation in which attempts were made to enhance the discriminability of perceptual stimuli through the attachment of distinctive labeling responses (for a review see Arnoult, 1957). Suffice it to say that such pre-differentiation procedures have met with rather limited success. At this point we shall confine ourselves to the description of a recent study by Underwood and Ekstrand (1968b) that focused on the question of whether a positive component of stimulus differentiation can appreciably reduce the amount of negative transfer in the *A-B, A-D* paradigm. The study took its point of departure from the assumption that the weight of this positive component should depend on the degree of intralist stimulus similarity. When the similarity is high, stimulus differentiation is difficult; hence transfer of the differentiation accomplished during first-list
Figure 21.15. The role of stimulus differentiation in transfer. Measures of transfer performance under conditions of low and high intralist stimulus similarity. To the extent that there is transfer of stimulus differentiation, performance under the *A–D* paradigm should become increasingly superior to that under the *C–D* paradigm as similarity changes from low to high. (Underwood &Ekstrand, 1968b.)

learning should be a source of considerable facilitation under the *A–D* as compared to the *C–D* paradigm. This advantage should be greatly reduced when interstimulus similarity is low and differentiation is easy. Three related experiments were carried out in which the learning materials were lists of six paired associates, with consonant trigrams as stimuli and common words as responses. The interstimulus similarity was either high or low. At each level of similarity a comparison was made between the *A–D* and *C–D* paradigms. The individual experiments differed only with respect to the criterion of first-list learning—one perfect recitation in the first experiment and three perfect recitations in the second and the third. Performance on the common transfer list is shown in Figure 21.15. As expected, the amount of negative transfer is less when interstimulus similarity is high than when it is low, but the effects are in general small and of borderline statistical significance. The investigators conclude that the transfer of stimulus differentiation is so slight that the subjects in the *A–D* condition apparently must start this process almost afresh in learning the transfer list. Thus, theoretical expectations regarding the role of this component are only weakly supported. It appears that it is difficult to separate stimulus differentiation per se from the acquisition of specific associations.

A–B, C–B Consideration of the *A–B, C–B* paradigm brings into sharp focus the role of response meaningfulness as a determinant of transfer. Response learning is a source of facilitation whereas interference between backward associations is a negative component in this paradigm. The relative weight of these two factors in determining the net transfer effect should depend on the meaningfulness of the responses: the lower the meaningfulness the greater should be the influence of the response learning relative to the associative component. Since the integration of responses from outside the subject's repertoire occupies a large proportion of the total learning time, the direction of the net transfer effect may be expected to shift from positive to negative as the meaningfulness of the responses varies from low to high. Precisely such a result was found in Jung's (1963) experiment when the meaningfulness of trigram responses to adjective stimuli was changed from low to high. The shift in transfer was from a large positive effect to a slight negative one. In general, experiments in which the responses were nonsense items have yielded some evidence of positive transfer (Bruce, 1933; Mandler & Heinemann, 1956; Dean & Kausler, 1964; Merikle, 1968), but there are exceptions (Harcum, 1953), and as will be seen shortly, the observed net effects may depend on the degree of first-list learning. With words as responses, there is usually a small negative effect (Twedt & Underwood, 1959; Dallett, 1962a; Postman, 1962a; Kausler & Kanoti, 1963; Goulet & Behar, 1966).

When negative effects are observed, the

question arises as to the mechanism by which a conflict between backward associations interferes with transfer learning. Any explanation must take account of the fact that the subject is not required to reproduce the stimulus terms while learning the second list; that is, the first-list backward associations do not constitute competing responses in the usual sense. Twedt and Underwood (1959) have suggested that during the acquisition of the transfer list the elicitation of first-list backward associations may cause the subject to withhold correct responses. The hypothetical mechanism is as follows: During transfer learning the subject may be about to give the correct *B* to a given *C*, but the activation of the old backward association *B–A* leads to the inference that *B* "belongs with" *A* rather than *C*. Consequently the response is erroneously rejected and withheld. In short, the backward association serves a "checking" function (see McGovern, 1964) and is used by the subject for purposes of editing his responses. One implication of this account is that the negative effects should be reduced if the stimulus terms in the successive lists are made highly distinctive, for example, are drawn from different classes such as letters and adjectives. This expectation was not confirmed in a study by Schwartz (1968); however, the absolute levels of transfer were too small to permit a sensitive test of the hypothesis. The prediction appeared to receive confirmation in an experiment by Olivier and Kausler (1966); but since stimulus dissimilarity and meaningfulness were confounded, the results cannot be regarded as conclusive. To the extent that the interpretation of Twedt and Underwood proves valid, the effectiveness of the interference from backward associations would have to be considered as dependent on the degree of list differentiation.

It should be recalled at this point that transfer effects have also been shown to be influenced by the relation between the backward association in the first list and the forward association in the second list, for example, *A–B, C–A* and *A–B, B–C*. When the two associations are symmetrical, that is, *A–B, B–A*, the effects are positive (Murdock, 1956; Palermo, 1961). When one member of the second-list pairs is new, as in the paradigms mentioned just previously, the transfer effects are negative (Harcum, 1953; Murdock, 1958; Goulet & Barclay, 1965; Houston, 1966a, b). In such cases inappropriate rejections of correct responses in the manner described by Twedt and Underwood would occur to the extent that subjects fail to distinguish between forward and backward associations. It is more likely that the change in the function of individual items, old stimuli becoming responses or vice versa, is an important source of confusion. The fact that double-function lists, in which each item serves as both a stimulus and a response, are much more difficult to learn than standard paired-associate lists is consistent with this interpretation, although backward associations must certainly be considered a major source of interference in this task (Primoff, 1938; Young, 1959; Young & Jennings, 1964).

A–B, A–Br Reference to Table 21.3 makes clear the presence of multiple negative components in the *A–Br* paradigm: forward and backward associations, and list differentiation. However, response learning is a source of facilitation. As in the case of *C–B*, we would, therefore, expect the net observed effects to vary with the level of meaningfulness of the responses, that is, to become increasingly negative as one moves from nonsense items to words. Such is, indeed, the case. With trigrams as responses, facilitation relative to the *C–D* baseline has been reported (Mandler & Heinemann, 1956) or relatively moderate negative effects which are not appreciably greater than for *A–D* (Jung, 1962). When the meaningfulness of trigram responses is changed from low to high, transfer effects shift from positive to negative (Merikle, 1968). When the responses are words, the amounts of negative transfer are typically very heavy and exceed those for *A–D* (Porter & Duncan, 1953; Besch & Reynolds, 1958; Twedt & Underwood, 1959; Postman, 1962a, 1964a; Kausler & Kanoti, 1963).

With respect to the interference falling on individual associations, *A–Br* may be seen as a combination of *A–D* and *C–B*. However, such an analysis is incomplete because neither the Cs nor the *D*s are in fact new but rather are old stimuli and old responses, and the items which they replace are still present in the list. Besch, Thompson, and Wetzel (1962) have suggested that during the acquisition of a re-paired list the associations of the stimuli with their former responses continue to receive some generalized reinforcement and consequently are resistant to extinction. As expected, they found that the re-paired items became less difficult to learn when the old responses to the stimuli were removed from the list. It is clear that for *A–Br,* more than for the other paradigms, it is not possible to specify the conditions of transfer without reference to the relations between lists rather than those which obtain for single pairs. As Table 21.3 brings out, the possibilities of list differentiation are minimized when old stimuli and responses are re-paired; this factor probably contributes to the persistence of the negative transfer effects.

Rank order of paradigms When the standard paradigms are compared within the same experimental situation, there are usually reliable differences in the direction and amount of transfer relative to the *C–D* control baseline. The differences are orderly in so far as they can be related to the number and assumed effectiveness of the component processes contributing to the net transfer effects. When the response terms are familiar units that do not require integration, the typical alignment of paradigms is as follows: *A–B′* is positive (at least early in transfer learning) and is followed, in order of increasing negative effects, by *C–B, A–D,* and *A–Br*. This order can be seen as consistent with the specification of component processes in the table above.

When English words are the responses, it may appear reasonable to suppose that the rank order of paradigms reflects primarily the operation of associative components. However, even in such cases response learning may be an important factor, in the limited sense of establishing the pool of responses to be used in the list. That is,
Figure 21.16. Acquisition of the transfer list under various paradigms when performance is tested by the recall method (left) and by the multiple-choice method (right). (Postman & Stark, 1969.)

response learning encompasses both item integration and item recall. Both subcomponents are relevant when the responses are from outside the subject's vocabulary, only the latter when they are familiar words. To assess the contributions to transfer of strictly associative components and of response recall, Postman and Stark (1969) compared two conditions of practice—one in which both associative learning and response recall were required and one in which the latter was minimized if not eliminated.

Two successive lists of 10 paired associates, with single letters as stimuli and adjectives as responses, were learned either by the recall method or the multiple-choice method. Under both procedures study trials were alternated with test trials. The difference between the two treatments was in the nature of the test trials. In the recall method the subject was required to reproduce the responses to each of the stimuli; in the multiple-choice method he had to choose the correct response to a given stimulus from among four alternatives, all of which were response terms from within the list. The three distractors accompanying a given correct item changed from one test to the next. First-list learning was to a criterion of one perfect recitation and was followed by ten trials on the second list. A comparison between the two methods of practice was made for all five of the standard paradigms discussed above. Performance on the transfer trials is shown in Figure 21.16. When the recall method is used, the differences among paradigms show the typical pattern. (However, *C–B* yields essentially zero rather than slightly negative effects; it is possible that the component of response recall is more important when study and test trials are alternated than under the anticipation procedure used in earlier studies.)

There are substantial changes in the alignment of the paradigms in the multiple-choice condition. The transfer effects for all experimental paradigms are now negative. Thus, there are shifts from zero to negative transfer for *C–B*, and from positive to negative effects for *A–B′*. The separation between *A–D* and *A–Br* occurs earlier than in the recall condition. The differences between the patterns of transfer effects under the two methods indicate that the positive factor of response recall serves to mask or to delay the manifestations of associative interference. This is true not only for the paradigms of response identity (*C–B* and *A–Br*) but also for *A–B′* where the responses are synonymous. The relation of synonymity (or associative connection) restricts the range of alternative responses in the recall method; once this positive factor is eliminated, the negative effects attributable to the confusion between words with similar meanings (or between mediators and mediated terms) become fully apparent and outweigh whatever positive components are present. The same negative effects are evident late in practice under the recall condition where *A–B′* falls below *C–D*. In general, the findings call attention to the fact that a precise analysis of transfer into its components depends on the development of methods of measurement that are differentially sensitive to the several constituent processes.

Degree of learning When each of the components of transfer represented in Figure 21.14 is considered separately, the observed effects may be expected to be an increasing function of the degree of first-list learning. Whatever the operative factor is, it will be developed more fully as practice continues. However, the analysis becomes far more complex when the influence of degree of training on the net transfer effects comes under scrutiny. The reason for the difficulty is that various sources of transfer may develop at different rates during first-list learning. Within the framework of a two-stage analysis, response learning is assumed to precede associative learning. Hence, response learning will be the dominant source of transfer at low levels of first-list practice, but at the higher levels, associative learning will carry increasing weight with the relative durations of the

two stages depending on the meaningfulness of the responses (see Martin, 1965). Add the fact that the components may influence transfer performance in opposing directions, as in the *C–B* paradigm, and it becomes apparent that a monotonic relation between degree of first-list learning and transfer effects is not necessarily to be expected.

The empirical evidence on this question is not extensive. We shall consider only studies of verbal transfer that include a control for warm-up and learning to learn (*C–D*), which is essential since nonspecific effects are known to increase with the amount of prior training. (It may be noted in passing that the omission of the necessary control condition is not entirely a thing of the past as witness a recent study of the relation between over-learning and transfer by Holborn and Boe, 1965). Since the relative contribution of response learning and of associative factors may be expected to vary with degree of first-list learning, the functional relations observed with materials of high and of low meaningfulness must be carefully distinguished. A study by Mandler and Heinemann (1956) will serve as a convenient point of departure for consideration of the latter. The learning materials in this experiment were paired associates with digits as stimuli and consonant syllables as responses. The first list consisted of four pairs and the second list of eight pairs. The transfer list was mixed and was so constructed that the following four paradigms were represented by two pairs each: *C–D, C–B, A–D, A–Br*. There were five levels of first-list learning: one group received no training and the others were carried to a criterion of either 10, 30, 50, or 100 errorless trials. Thus, the effects of varying degrees of overlearning on transfer were examined. These effects are summarized in Figure 21.17. The upward trend for *C–D* reflects progressive increases in nonspecific transfer. Both conditions of response identity (*C–B* and *A–Br*) show increasing amounts of positive transfer, indicating that the response-learning component outweighs associative interference. A rather unusual feature is the finding of greater positive transfer effects for *A–Br* than for *C–B*. The explanation probably lies in the fact that only two pairs were used per paradigm. If the subjects could identify the two stimuli whose responses had been re-paired, the presentation of the first pair conveyed full information about the correct response in the second. As for the *A–D* paradigm, the function is somewhat erratic and yields no statistically reliable differences; note, however, the reversal in the initial trend toward increasingly negative transfer. The authors suggest that this apparent reduction in negative transfer reflects the development of "symbolic analogues" of the first-list associations at the higher levels of overlearning which facilitate implicit trial-and-error. Such an intervening process presumably permits the rejection of incipient errors and thereby reduces interference. A further discussion of this interpretation of the effects of overlearning on transfer may be found in a theoretical paper by Mandler (1962) and in
Figure 21.17. Transfer performance as a function of the degree of first-list learning. The stimuli were single digits, and the responses were consonant syllables. To take account of differences in item difficulty, the data were corrected to permit plots from a common origin. Note that the curve for the control condition (*C–D*) represents actual changes in performance, whereas transfer measures (differences between scores on experimental and control pairs) are shown for the other paradigms. (Mandler & Heinemann, 1956.)

a subsequent interchange between Jung (1965) and Mandler (1965).

The fact that the results of Mandler and Heinemann yield no evidence of a gradual build-up of associative interference in the *C–B* condition is of theoretical interest. The evidence for such a build-up is also minimal in the study of Jung (1962), which compared the same four paradigms but used lower degrees of first-list learning. With adjectives as stimuli and trigrams as responses there was no reliable transfer for the *C–B* condition (the effects for *A–Br* as well as *A–D* were negative, but the level of meaningfulness was probably higher than in the earlier study). Under the conditions of response identity there is a slight trend in the direction of greater negative effects as the degree of first-list learning increases, but the trend is far from significant. Other findings for the *C–B* paradigm, which bear on the question of the development of associative interference, are inconsistent. As noted earlier, there was some apparent increase in positive transfer as a function of degree of first-list learning in Bruce's (1933) data. On the other hand, Dean and Kausler (1964) reported a shift from positive to negative transfer effects as the level of practice on the first list was increased. The fact that Harcum (1953) found negative transfer for the *C–B* paradigm after a high degree of first-list learning is also relevant here. It should be noted that the three studies mentioned last all used paired nonsense syllables in the successive lists. Because of the inevitable overlap of elements both within and between lists, the similarity relations under these conditions are likely to be very complex and also variable from one experiment to the next. The use of such materials for purposes of isolating particular components of specific transfer is, therefore, inadvisable. Taken together, the experiments considered in this section confirm the importance of response learning as a source of transfer but do not shed much light on the development of associative effects.
Figure 21.18. The effect of degree of first-list learning on transfer, with paired adjectives as the learning materials. The degree of first-list learning is scaled in terms of the number of reinforcements (correct anticipations) during acquisition. (Postman, 1962a.)

Figure 21.18 shows the result of an experiment (Postman, 1962a) that investigated the relation between degree of first-list learning and transfer with materials of high meaningfulness, namely, lists of paired adjectives. The first list was learned either to a criterion of 6/10, to 10/10, or to 10/10 plus 50 percent overlearning. The negative transfer effects for *C–B* and *A–D* first increase and then decrease; by contrast the trend is monotonic for *A–Br*. However, the interaction of paradigm with degree of first-list learning fails to reach significance. If the trends are taken at face value, a likely explanation for the divergence of *A–Br* from the other two paradigms is the failure of list differentiation to counteract increased interference from both forward and backward first-list associations. List differentiation may be expected to increase with degree of first-list learning (see Underwood, 1945) but would develop most slowly when both the stimulus and the response terms remain the same.

Mandler's (1962) hypothesis that overlearned first-list associations form analogic structures that function to reduce interference was tested in an experiment by Spence and Schulz (1965). The first list, which was composed of strongly associated pairs (nor-

mative primaries), was presented for either 1, 5, 20, or 40 trials. The pairs in the second list (*A–D*) had a minimal degree of pre-experimental associative connection. Negative transfer relative to a control condition increased as the number of first-list trials went from one to five and remained relatively constant thereafter. Neither high associative strength nor protracted practice was sufficient to produce the reduction in interference predicted by Mandler. List differentiation was probably maximal at all levels of practice in view of the very large differences in associative strength. Other experiments in which the V-shaped function for *A–D* transfer implied by Mandler failed to materialize do not bear critically on the hypothesis because low degrees of first-list learning were compared (Schulman, 1967), different methods of practice were used in the successive lists (Goulet, Meltzer, & O'Shaunessy, 1967), or both (Goulet, 1967).

The most important conclusion to be drawn from these studies is that increases in negative transfer effects are not proportional to the degree of first-list learning. It appears that the amount of interference is a negatively accelerated increasing function of the strength of the competing associations. Hence increments in first-list strength yield diminishing returns. In addition, positive factors may come into play to counteract the growth of interference. There is little support for Mandler's hypothesis inasmuch as the development of the postulated structures is seen as critically dependent on degree of associative strength per se. Whether such factors as list differentiation do in fact mitigate associative interference is still an open question.

Unmixed versus mixed transfer designs When we speak of a paradigm of transfer, we refer to the rule governing the relation between pairs in the successive lists. It is reasonable to suppose that a subject who can identify this rule and attempts to conform to it would be aided in his performance of the transfer task. For example, in learning a *C–B* list he would limit himself to the repertoire of *B*'s already available to him, whereas he would withhold old responses in an *A–D* condition. Such strategies can be carried out effectively as long as the transfer list is unmixed, that is, all the pairs represent the same paradigm. When the transfer list is mixed, so that subgroups of pairs conform to different paradigms, the implementation of paradigmatic rules clearly becomes more difficult because it depends on the subject's ability to classify the individual pairs according to the relation which they bear to the first list. On the basis of these considerations, transfer performance would be expected to be superior when unmixed rather than mixed lists are used. The experimental facts have, however, given only limited support to this expectation. A systematic comparison between the results obtained with unmixed and mixed lists was made by Twedt and Underwood (1959) for the *C–D, C–B, A–D,* and *A–Br* paradigms. The transfer effects obtained under the two conditions of testing were essentially identical. Thus, the differential opportunity for applying a consistent rule to all the pairs in the list was not reflected in performance. Either the subjects learning the unmixed lists did not attempt to apply the appropriate rule, or if they did, this strategy had no discernible influence on learning.

The possibility remained open, however, that the picture would change if a different grouping of paradigms were used in the mixed list. All the paradigms used by Twedt and Underwood yielded negative transfer effects, and none of the implied rules specified the correct responses to individual stimuli; rule-governed behavior may not have provided an effective guide to performance. To explore this possibility, Postman (1966) included a condition of positive transfer among those used in a comparison of unmixed and mixed designs. There were again four paradigms: *C–D, C–B, A–D,* and *A–B′*, the last of these representing the condition in which a mediational rule was available. The

unmixed condition resulted in better transfer performance for all paradigms except *C–D*. However, the differences, while consistent, were small. It appears, then, that the differences in the amount of transfer obtained with mixed and unmixed lists depend on the range of paradigms included in the design.

This conclusion receives strong confirmation from the results of a recent study by Wickens and Cermak (1967) in which the effects of different similarity relations between responses were evaluated in unmixed and mixed transfer designs. Successive responses to identical stimuli were either synonyms, antonyms, or unrelated. The most noteworthy finding was that when the responses in the two lists were antonyms, the transfer effects were clearly positive for unmixed lists but shifted to negative in the mixed condition. As the authors point out, antonymity implies a mediational rule that can be applied during the acquisition of an unmixed transfer list. In a mixed list the rule cannot be applied effectively, and antonymous responses behave like unrelated ones (*A–D*). By contrast, the transfer effects remained positive for synonyms under both unmixed and mixed test conditions; the authors view this fact as consistent with the hypothesis of response generalization. A report by Slamecka (1967) is in sharp disagreement with these findings. In the experimental paradigms the stimuli remained the same and the response words were either identical, synonyms, antonyms, or re-paired (*A–Br*). The transfer effects remained positive for antonyms as well as synonyms in both mixed and unmixed lists. However, these data are difficult to interpret for a number of reasons. Trigrams were used as stimuli in successive 20-pair lists, so that there probably was considerable interference under the control (*C–D*) condition. The atypical absence of negative transfer in the *A–Br* paradigm in the case of the unmixed list indicates that the control baseline may, indeed, have been seriously biased, and perhaps differentially so under the mixed and unmixed treatments. Moreover, the testing rate was subject-paced, and the possibility of differential rehearsal on test trials cannot be excluded. Hence Slamecka's conclusion, based on the lack of differences between transfer effects under the unmixed and mixed conditions, that subjects do not in fact use mediational rules, may be regarded as premature.

Acquisition of transfer skills Higher-order habits in the performance of transfer tasks, such as the systematic application of paradigmatic rules, have also received attention in studies of learning to learn. It has been found that repeated experience with a given paradigm enhances the efficiency of performance in the transfer stage. The magnitude of the gains in performance varies with the nature of the paradigm: there are greater increases in positive transfer (*A–B′*) than there are decreases in negative transfer (*A–D* and *A–Br*). The very substantial improvements in the *A–B′* condition point to increased efficiency in the utilization of the appropriate mediational rule (Postman, 1964a). The effects of experience in the performance of transfer tasks appear to be highly generalizable since the amount of improvement is equal when the paradigms used in the training and the test phase remain the same and when they change (Keppel & Postman, 1966; Martin, Simon, & Ditrichs, 1966). This conclusion must, however, be limited to standard paradigms such as *A–B′* and *A–D* in which the appropriate response rules are readily identified. When the intertask relations are more complex, as in the three-stage chaining paradigms to be discussed shortly, the effects of training are specific to the particular paradigm with which the subject has had prior experience (Postman, 1968b).

HIGHER-ORDER MEDIATION

For purposes of introducing the topic of higher-order mediation it is useful to refer back to the standard *A–B, A–B′* condition. As far as the experimental arrangements are con-

TABLE 21.4

	Paradigm							
	I	*II*	*III*	*IV*	*V*	*VI*	*VII*	*VIII*
Stage 1	*A–B*	*B–D*	*B–A*	*D–B*	*A–B*	*D–B*	*B–A*	*B–D*
Stage 2	*B–D*	*A–B*	*D–B*	*B–A*	*D–B*	*A–B*	*B–D*	*B–A*
Stage 3	*A–D*	*A–D*	*A–D*	*A–D*	*A–D*	*A–D*	*A–D*	*A–D*

cerned, this is a two-stage paradigm since the procedure is confined to the acquisition of two successive lists. However, to the extent that mediational chaining is invoked as an explanation of the observed transfer effects, a third stage of learning is implied, which has occurred prior to the experiment: the development of an associative connection between *B* and *B′*. When the implied conditions of prior learning are taken into account, *A–B, A–B′* is seen to represent a three-stage paradigm of transfer:

Stage 1	*B–B′*
Stage 2	*A–B*
Stage 3	*A–B′*

This schema exhibits the defining property of a mediate association: When two terms (*A* and *B′*) are each independently associated with a third (*B*), an associative connection develops between these two terms. Thus, the association *B′* to *A* may be available at the beginning of Stage 3 even though this pairing has not occurred previously. The association between *A* and *B′* is indirect and depends on a common third term (*B*), which is linked separately to each of them.

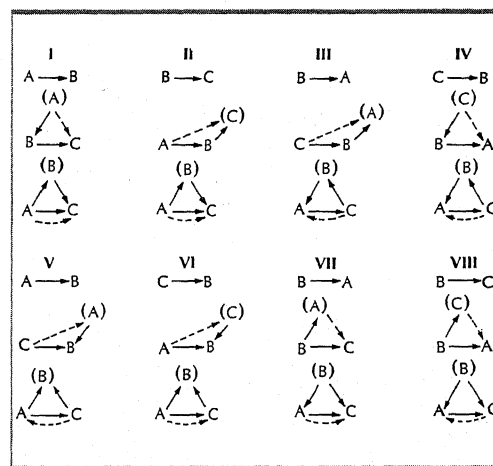
The concept of mediate association arose early in the history of association theory (see Peters, 1935, pp. 20–25); in contemporary psychology it has been endowed with considerable theoretical significance by its systematic application in the analysis of secondary generalization and problem solving by behavior theorists (see Cofer & Foley, 1942; Goss, 1961). An early attempt by Peters (1935) to demonstrate verbal mediation was largely unsuccessful, but the problem was reopened by Bugelski and Scharlock (1952), who obtained positive results of borderline significance and also found that mediational processes may occur without apparent awareness on the part of the subject. Largely under the influence of Jenkins and his associates, the last decade has produced a large volume of experimental work on multiple-stage mediation in transfer. There have been several extensive reviews of this research (Jenkins, 1963b; Earhard & Mandler, 1965a; Horton, 1967; Kjeldergaard, 1968). We shall now consider some of the major experimental findings and theoretical issues.


Figure 21.19. Analysis of the associative links assumed to be established under each of 8 paradigms of mediation. ⟶ and ⟵ indicate explicit forward and backward associations, respectively. ( ) denotes an hypothesized implicit response, - - -→ a presumed implicit forward association, and ←- - - a presumed implicit backward association. (Horton & Kjeldergaard, 1961.)

Paradigms of Three-stage Mediation

When three lists of paired associates are learned in succession, and three of the terms occur in two lists each, a possibility of mediated transfer exists. The associative relations that have to come into play in order to permit mediation depend on the arrangement of the individual terms. Eight paradigms of three-stage mediation (Horton & Kjeldergaard, 1961) are reproduced in Table 21.4. The table should be considered along with Figure 21.19 which depicts the implicit responses and mediating links assumed to function in each of the eight situations.

These eight paradigms form three distinct groups. Conditions I, II, III, and IV are chaining paradigms; in such paradigms the term common to the first two stages occupies the stimulus position in one of the lists and the response position in the other. For example, in condition I a mediational chain is assumed to function because after acquisition of *A–B* in the first stage the backward association *B–A* is elicited during the second stage, allowing *A* and *D* to become associated. Alternatively, or in addition, the associations learned during the first two stages are put together during the test stage to yield the chain *A–B–D*. In the remaining paradigms the common term occupies the same position in the first two stages. Conditions V and VI represent paradigms of acquired stimulus equivalence. That is, *A* and *D* become equivalent by virtue of the fact that they both elicit *B* as a forward association. Finally, conditions VII and VIII are paradigms of response equivalence: *A* and *D* become equivalent because they are both responses to *B*.

In developing predictions about the relative efficacy of the various paradigms, Horton and Kjeldergaard focused on two characteristics of the mediational links, namely, directionality and contiguity. Greater transfer effects are predicted when the mediated links between *A* and *D* established in the second stage are in the forward rather than the backward direction. On this basis paradigms I, II, VI, and VII should be superior to III, IV, V, and VIII. For example, in paradigm I the assumed sequence of events in the second stage is *B*–(*A*)–*D*; in paradigm III it is *D*–*B*–(*A*). More transfer is also expected when the inferred associative sequence in stage 2 places *A* and *D* in direct juxtaposition than when they are separated by another term. This factor of contiguity favors paradigms I, IV, VII, and VIII over II, III, V, and VI. The sequences for paradigms I and III again provide relevant examples. Directionality is assumed to have greater weight than contiguity in determining performance. The final predicted rank order, which takes account of both characteristics, comprises four groups. In descending order these are: I and VII; II and VI; IV and VIII; III and V.

It should be noted that the predictions are based on the assumed properties of the mediational links established in the second stage. However, the implicit associations may not develop in the second stage but may be entirely a test-stage phenomenon, that is, during the acquisition of the test list the subject may use what he has learned previously to generate a link between *A* and *D*. The functional links in the second and the terminal stage may have different properties; to the extent that they do, the predictions above do not apply to test-stage mediation. For example, in paradigm I the establishment of an *A–D* link depends on the elicitation of the backward association *B–A*. In test-stage mediation only forward links are required to complete the chain from *A* to *B* to *D*. The lack of critical operations for resolving the uncertainty about the locus of mediation remains a persistent source of interpretative difficulties.

Inspection of the table of paradigms at once calls attention to another basic problem of interpretation. When we consider the stages of the various paradigms in pairs, we encounter in many cases the familiar two-stage paradigms of negative transfer. For example, associative interference is indicated for all three of the possible pairings of the

stages in paradigm I: *A–B, B–D; A–B, A–D; B–D, A–D*. Thus, mediational and interference effects must be expected to develop in opposition to each other, and whatever facilitation is observed in the test stage represents a residual effect. In studies of mediation an attempt is made to take account of other sources of transfer by comparing the experimental treatment with an appropriate control condition. In the latter the common term assumed to provide the critical associative link is removed. The sequence of lists in the control treatment for paradigm I is either *A–X, B–D, A–D* or *A–B, X–D, A–D*. The experimental-control difference in the test stage provides a measure of mediation. It should be clear from our previous discussion, however, that the amount of negative transfer in second-stage learning will be greater for the experimental than for the control treatment. The two conditions are, therefore, not in fact equal in all respects except for the possibility of mediation. We shall return to some important implications of this state of affairs shortly. At this point it is useful to emphasize that performance in the successive stages of all the paradigms is complexly determined and that the isolation of mediational effects poses difficult analytic problems.

In typical studies of mediation three successive lists of paired associates are learned which conform to the appropriate experimental or control paradigm. While the degrees of first-list and second-list learning are variables manipulated in some experiments, these lists are normally carried to a high criterion in order to ensure the stability of the mediating associations. An alternative procedure has been used in a series of studies by M. J. Peterson and her associates (for example, Peterson & Blattner, 1963; Peterson, Colavita, Sheehan, & Blattner, 1964; M. J. Peterson, 1964, 1965; Peterson & Jamison, 1965). The pairs representing the first two stages are given a limited number of exposures (sometimes only one), and the test stage consists of a multiple-choice procedure in which the stimulus term (*A*) is presented with three alternatives including two distractors (new terms) and the mediated response (*D*). The subject is instructed to pick the alternative which seems to him to "go best" with the stimulus term. The method has the advantage of eliminating test-stage learning and thus provides a relatively pure test of mediational effects. Apparent disadvantages are the inevitable ambiguity of the instructions and the fact that subjects are likely to choose a familiar term under both the control and the experimental condition. Consequently, the test procedure may have rather limited sensitivity, which may account for occasional unexpected failures to observe reliable mediational effects, for example, for the chaining paradigms (Peterson et al., 1964).

Four-stage Paradigms

The length of the mediational sequence can be extended to generate four-stage paradigms. Such paradigms are of theoretical interest because they constitute possible models of higher-order transfer effects related to stimulus equivalence and to response equivalence. A sequence illustrating transfer that is contingent upon acquired stimulus equivalence is as follows: *A–B, C–B, A–D, C–D* As stated earlier, *A* and *C* are assumed to become equivalent stimuli during the first two stages because they both elicit the same response (*B*). By virtue of this equivalence a new response (*D*) associated with *A* is expected to be evoked by *C*. Presumably elicitation of the common implicit response *B* during the last two stages provides the mechanism of transfer. This paradigm was used earlier by Shipley (1935) in a well-known experiment in which mediated generalization of a conditioned eye-blink response was demonstrated.

The following four stages exemplify the development of response equivalence as a result of the prior establishment of a mediational chain: *A–B, B–C, D–A, D–C*. A chain leading from *A* to *C* is established during the first two stages. In the third stage *A* is attached as a

response to a new stimulus (*D*). In the final stage *C* is attached to the same stimulus. Given the association *D–A*, the completion of the chain *A–B–C* should facilitate the acquisition of *D–C*. As will be seen later, this paradigm has been used extensively in the evaluation of transfer effects attributable to pre-experimental linguistic associations. These examples should be sufficient to indicate the characteristics of four-stage paradigms. Extensive tables of possible arrangements have been presented by Jenkins (1963b, pp. 218f).

Experimental studies of mediation may be conveniently divided into two major classes: those in which all stages are acquired in the laboratory and those in which one or two of the stages are assumed on the basis of normative information about pre-experimental associations. We consider the former first.

Studies of Three-stage Mediation: All Associations Acquired in the Laboratory

A major experimental investigation under this heading was carried out by Horton and Kjeldergaard (1961). All eight of the paradigms listed in the table above were included in the design. The learning materials were lists of eight paired associates; both stimuli and responses were words of very low frequency of usage. A mixed-list design was used, with half of the pairs in the final test lists being experimental pairs and half control pairs. The purpose of the study was to demonstrate the occurrence of mediational effects and also to test the predictions, mentioned earlier, about the relative effectiveness of the various paradigms in producing mediation. Significant amounts of mediated facilitation were obtained for all but one paradigm (the exception was condition III). There was only limited support for the predictions regarding the rank order of paradigms. While the differences generally were in the expected direction, primarily with respect to directionality, the interaction of treatment (experimental versus control) and paradigm was not significant. Post-experimental inquiries failed to yield any evidence of awareness on the part of the subjects of the interlist relations permitting mediation. Analysis of individual differences indicated that the amount of mediation was greatest for subjects of intermediate, but above average, learning ability as measured by performance in the first stage.

In subsequent studies reports of reliable differences among paradigms have been few and far between, but there are indications that paradigm I (forward chaining) is superior to the other conditions (Seidel, 1962; Horton & Hartman, 1963; Shanmugam & Miron, 1966). However, the multiple-choice procedure appears to favor the stimulus-equivalence and response-equivalence paradigms (Peterson et al., 1964). In general, the original predictions regarding the rank order of paradigms have received little empirical verification. While the available data do not rule out the possibility that directionality is a significant factor, the effectiveness of backward associations in producing mediation has been repeatedly demonstrated (for example, McCormack, 1961; Palermo, 1966).

Since mediation is a special case of transfer, the variables of meaningfulness and degree of learning deserve special attention. There are reasons to expect a mediator of high meaningfulness to be more effective than one of low meaningfulness; the former has the advantage of greater availability and distinctiveness. This prediction has been confirmed (Horton, 1964). Closely related is the finding of Shanmugam and Miron (1966) that the degree of semantic polarization of the mediator has a positive influence on mediated transfer. In the experiments of Peterson and her coworkers using the multiple-choice technique greater effects were obtained when the total pool of materials, that is, all the terms in the successive lists, were of high rather than low meaningfulness. A general methodological point is in order here. There has been a disposition on the part of many investigators to use nonsense items or words of very low frequency as the terms to be linked by the mediator; such items have also

been used as the critical common terms. An apparent reason for the choice of such materials is the desire to minimize pre-experimental associations. It is uncertain to what extent this objective is achieved since nonsense items are certainly not free of such associations. An apparent disadvantage is that speed of acquisition is heavily influenced by response learning, so that the experiment becomes relatively insensitive to mediational effects that are entirely associative. If the mediator itself is a nonsense item, it may fail to function because of low availability or discriminability. Some failures to observe mediated transfer may reasonably be attributed to this state of affairs. For example, Crawford and Vanderplas (1959) used difficult lists of paired nonsense syllables in all stages of their experiment and found no evidence at all of mediational chaining (paradigm II). The result is perhaps not surprising when it is noted that a naive control group took nearly 42 trials to learn the test list to a criterion of three perfect recitations. To minimize the influence of the factor of response learning, Schulz and his associates (for example, Schulz & Weaver, 1968) have used a multiple-choice learning procedure in the second and third stages.

The available evidence on the relation between degree of learning in the first two stages and effectiveness of mediation is not impressive. Horton and Hartman (1963) varied the number of trials in both stages concomitantly and reported a positive effect; in the absence of appropriate control groups, however, the findings cannot be evaluated. Shanmugam and Miron (1966) observed increases in transfer as a function of degree of second-stage learning. Schulz and Weaver (1968) manipulated frequency of exposure to first- and second-list pairs independently but did not detect any changes in mediation. Finally, in the multiple-choice situation variations in the frequency of exposure of the pairs appears to have no reliable effect on mediation (Peterson & Blattner, 1963; M. J. Peterson, 1963, 1964). Since the first-list pairs are subject to interference during second-stage learning, it appears likely that in a given situation there is a ratio of first-list to second-list strength which is optimal for mediation. Some data reported by Kjeldergaard (1968) are consistent with this assumption.

Interference paradigms A sensitive test of the effectiveness of mediators is provided by the use of paradigms in which the assumed associative links should retard, rather than facilitate, test-list learning. Such an interference paradigm is created when the stimulus and response terms in the second stage are paired inappropriately, for example, in the case of the forward-chaining condition, *A–B, B–Dr, A–D*. To the extent that mediation occurs in the test stage, it must lead to misplacement of responses. If we limit our consideration to three-stage paradigms for which all stages are established in the laboratory, the findings are contradictory. Some investigators found no difference between the interference and the control treatment (Jeffrey & Kaplan, 1957); some reported the expected negative effects (Morning & Voss, 1964; Horton & Wiley, 1967b), while still others observed differences in the opposite direction (Earhard & Mandler, 1965b; Earhard & Earhard, 1967). The importance of the interference paradigm for the theoretical interpretation of mediation effects will receive further consideration below.

Studies of Four-stage Mediation: All Associations Acquired in the Laboratory

Jenkins (1963b) reports a major experiment in which the effectiveness of 16 four-stage paradigms was examined. Eight paradigms each were used to test the predicted effects of acquired stimulus equivalence and of acquired response equivalence; the materials and procedure of Horton and Kjeldergaard (1961) were duplicated in most respects. Not a single paradigm yielded a significant amount of mediation. The results suggested that by the time the test stage is reached, the critical implicit response is weak and not

likely to be elicited; but even if it does occur, it has little functional utility. Consequently mediation is not reinforced and may indeed be inhibited. It is reasonable to suppose that in most cases the test list can be learned more efficiently with the aid of new and shorter mediational links developed from pre-experimental linguistic associations.

Subsequently some successful demonstrations of four-stage mediation have been reported under conditions designed to counteract the difficulties inherent in the situation, notably the probable weakness of the mediator at the time of the test. In the study of James and Hakes (1965) a paradigm of acquired stimulus equivalence (*A–B, C–B, A–D, C–D*) was used. The subjects relearned the earlier lists before the final test stage which consisted of a matching task. A substantial amount of facilitation was found which appeared to be limited to subjects who reported the deliberate use of a mediational strategy. The same paradigm was used by Grover, Horton, and Cunningham (1967) whose procedure also included relearning of earlier lists in the course of practice. Both facilitation and interference were observed, each with the appropriate version of the paradigm, in this case without evidence of awareness on the part of the subjects. It appears that four-stage paradigms are effective only when special care is taken to maximize the opportunities for mediation.

Pseudomediation?

Attention has already been called to the fact that conditions of negative transfer obtain between successive lists in the various paradigms. Using this fact as a point of departure, Mandler and Earhard (1964) advanced the hypothesis that apparent mediated transfer may be an artifact attributable to differences in test-stage interference between the experimental and the control conditions. The argument may be exhibited with reference to the three-stage paradigm of forward chaining. The sequence of lists is *A–B, B–D, A–D* for the experimental group, and *A–B, X–D, A–D* for the control group. *A–B, B–D* is a condition of negative transfer in which there is interference between the first-list backward and second-list forward associations. Mandler and Earhard assume that as a result of interlist interference the first-list associations (forward as well as backward) are unlearned during the acquisition of the second list in the experimental condition. No such unlearning occurs under the control condition. Consequently, the acquisition of *A–D* during the test stage is subject to less interference from *A–B* under the experimental than under the control treatment. Hence the difference between the two groups may represent nothing more than differential interlist interference. If such is, indeed, the case, it also follows that the interference paradigm should yield superior rather than inferior performance by the experimental as compared to the control group. The hypothesis is developed and applied to existing experimental findings in a theoretical paper by Earhard and Mandler (1965a).

To test the implications of this argument, Mandler and Earhard (1964) used a design in which the first two stages were the same as in the conventional paradigm, but mediation in the third stage was made impossible by the introduction of a new response term. Thus, the sequence of lists is *A–B, B–D, A–E* under the experimental treatment, and *A–B, X–D, A–E* under the control treatment. A significant difference in favor of the experimental group was obtained in the test stage. This effect was designated as pseudomediation. In a subsequent study Earhard and Mandler (1965b) also observed the expected superiority of the experimental group when the conventional interference paradigm was used. In their general review of the literature Earhard and Mandler (1965a) suggest that pseudomediation is responsible for the mediational effects obtained on the basis of successive associations established in the laboratory. When the associations are highly overlearned, notably if they represent pre-experimental language habits, or when the

memory requirements of the task are reduced, genuine mediation may occur. In such cases, however, the observed effects are attributed to the utilization by the subject of conceptual rules entailed by the experimental paradigms.

The pseudomediation hypothesis gave rise to a spirited controversy. The relevant evidence is summarized by Horton (1967) in a refutation of the analysis of Mandler and Earhard. We shall outline briefly the main empirical and theoretical objections to the pseudomediation hypothesis. (1) The assumption that first-list associations are unlearned under the experimental arrangements of the mediation paradigms has minimal empirical support. Direct tests of this assumption have yielded largely negative results (Jenkins & Foss, 1965; Carlson, 1966; Goulet, 1966); the one exception is an experiment by Earhard and Mandler (1965b) in which a test of associative matching was used. The latter is not representative of the usual conditions under which mediated transfer is measured. (2) The phenomenon of pseudomediation itself is difficult to replicate. There have been both unsuccessful (Schulz, Weaver, & Ginsberg, 1965; Goulet & Postman, 1966) and successful (Carlson, 1966; Earhard & Earhard, 1967) attempts at replication of the original finding of Mandler and Earhard. The indications are that the occurrence of the effect is contingent on the absence of intertrial intervals during learning. The matter is further complicated by the fact that pseudomediation effects may appear only in the later stages of test-list learning. By contrast, early test trials are typically most sensitive to mediational effects. (3) Comparisons of mediation and pseudomediation within the same design have yielded inconsistent results. Two studies obtained evidence only for the former (Schulz, Weaver, & Ginsberg, 1965; Goulet & Postman, 1966); Carlson (1966) found both effects to be of the same order of magnitude; Earhard and Earhard (1967) also observed both effects, with mediation superior. (4) As was indicated earlier, the evidence obtained in investigations of mediated interference is contradictory. The outcome of such studies is critical because the alternative theoretical positions generate diametrically opposed predictions. The available data give unequivocal support to neither position. (5) There is growing evidence that after test-list learning first-stage pairs are recalled better under the experimental than the control condition (Horton & Wiley, 1967a, b; Schulz, Liston, & Weaver, 1968). Apparently such pairs acquire strength through mediation. This finding is clearly consistent with the mediation but not the pseudomediation position. (6) The boundary conditions between pseudomediation on the one hand and mediation based on conceptual strategies on the other remain uncertain and difficult to apply. It is fair to conclude that some pseudomediation effects may occur under highly circumscribed experimental arrangements. The attempt to account for mediated transfer in its entirety in terms of pseudomediation appears to be without merit.

Three-Stage Mediation: One Stage Assumed

We now turn from experiments in which all stages of the mediation paradigm are established in the laboratory to those in which at least one stage is assumed to be given on the basis of associative norms. It should be noted first, however, that there are some studies which represent a transition between these two classes of operations; in such cases one or two of the stages consist of pre-experimental associations that are presented to the subjects in the form of learning tasks. This procedure has been favored in studies of mediation with children as subjects (Norcross & Spiker, 1958; Wismer & Lipsitt, 1964; Palermo, 1966) and has provided successful demonstrations of both mediated facilitation and interference. One advantage of the method is that it ensures the activation in the experimental context of the relevant pre-experimental associations; if the latter are strong, the attainment of the learning criterion is, of course, quite rapid.

Presentation of pre-experimentally related terms may also serve to activate and render functional associations which are relatively low in the subject's hierarchy. For example, groups of nouns can be categorized reliably on the basis of certain sensory categories shared by them (Underwood & Richardson, 1956); however, the names of the categories have a low probability of being elicited as associates by individual nouns. In a series of experiments by Richardson (1962; 1966a, b; 1967a) the conditions were explored under which such concept names could serve as effective mediators in a forward chaining paradigm. Specifically, a syllable (*A*) would be paired with one or more examples of the category (*B*), and in the test stage the syllable was paired with the category name (*D*). Presentation of the examples paired with the category names (*B–D*) proved to be an essential condition of mediated facilitation.

The first stage remains entirely implicit when the *A–B, A–B′* paradigm is used. As already noted, when the relation between *B* and *B′* is defined in terms of the degree of associative connection, substantial amounts of positive transfer are obtained. When the response terms are paired inappropriately, heavy associative interference is observed (Jenkins, Foss, & Odom, 1965). In fact, in the study just cited, the amount of negative transfer was comparable to that for the *A–Br* paradigm and greater than for *A–D*. Thus, the effectiveness of forward chaining in producing mediated transfer is substantiated when one of the stages is established pre-experimentally. All eight conditions used by Horton and Kjeldergaard (1961) were investigated by Cramer (1967) in an experiment in which the first stage of each paradigm was assumed on the basis of associative norms, and the appropriate second and third lists were learned in the laboratory. In general, there was good correspondence between her results and those of the earlier study. The rank order of the various paradigms confirmed the importance of the factor of directionality: Mediated transfer was greater when the experimentally acquired associations functioned in the same direction in the test stage as in the training phase than when the direction was reversed.

Four-Stage Mediation: Two Stages Assumed

A well-known experiment by Russell and Storms (1955) offered evidence for four-stage mediation, with the first two stages established pre-experimentally. The two lists learned in the laboratory had identical nonsense-syllable stimuli but different English words as responses. For the experimental pairs the responses in the first and the second list were the initial and the final terms, respectively, of a three-link associative chain. Thus, *cef-stem* was followed by *cef-smell.* According to free-association norms *flower* is the primary response to *stem,* and *smell* is in turn the primary response to *flower;* however, *smell* is not a likely direct associate to *stem.* Second-list learning should be facilitated to the extent that the pre-existing associative chain mediates the correct response during second-list learning: *cef-stem-(flower)-smell.* The paradigm is *A–B, B–C, D–A, D–C,* where *A–B–C* is the normative chain, and *D–A, D–C* are the associations learned in the laboratory. For the control pairs there was no known associative relation between the successive responses. Using a mixed-list design, Russell and Storms found that the experimental test pairs were learned faster than the control pairs (the two sets of pairs were shown independently to be of equal difficulty when there was no opportunity for chaining). The interpretation of the observed difference proved, however, to be far from simple. It was not certain whether associative chaining or enhanced availability of the responses was responsible for the superiority of the experimental pairs; nor to what extent there was absolute facilitation under the experimental treatment or merely reduced interference.

These questions were considered in a subsequent experimental analysis of the Russell-Storms effect by McGehee and Schulz (1961).
Figure 21.20. Test-list performance in the study of mediation by McGehee and Schulz (1961). For a description of the various experimental treatments see text.

The following four conditions were compared in an unmixed-list design: (1) A_2–B, A_2–D; (2) A_2–X, A_2–D; (3) A_1–B, A_2–D; (4) A_1–X, A_2–D. Condition 1 represents the experimental pairs used by Russell and Storms (*B–C–D* assumed), and condition 2 the control pairs. Note that a common test list is now used. In condition 3 different stimuli (A_1 and A_2) are used in the two lists in order to assess the possible effects of response availability per se. That is, this condition makes it possible to determine whether the prior practice with *B* terms facilitates the subsequent use of the *D* terms as responses. Condition 4, in which both stimuli and responses change, provides the standard control baseline. The results of the experiment are shown in Figure 21.20. Relative to the baseline condition (4), there is substantial associative interference in the acquisition of the Russell-Storms control pairs (2); the mediational effect for the experimental pairs (1) was apparently sufficient to counteract the interference but did not yield absolute facilitation. The advantage of the experimental pairs cannot be attributed to enhanced response availability since conditions 3 and 4 did not differ. In a second experiment evidence for mediated interference was obtained when the experimental pairs were paired inappropriately in the first list (A_2–Br).

Further experimental studies leave some doubt as to whether implicit mediation is the mechanism responsible for the differential transfer effects originally observed by Russell and Storms. Results reported by Martin and Dean (1964) indicate that experimental pairs have an advantage only to the extent that they elicit more explicit mediators (that is, mediators the subject can verbalize) than do the control pairs; however, the reported mediators often do not correspond to the normative ones. In the absence of explicit mediators experimental and control pairs do not differ. The results of a recent study by Richardson (1968a) likewise point to the conclusion that the assumed mediational chains frequently fail to be used. Judgments of congruence between the first-list and second-list responses were obtained; the most frequent matches did not correspond to the normative pairings. These judgments yielded better predictions of transfer than did the association norms, but the differences between experimental and control pairs were found to be small throughout. In light of the recent evidence the Russell-Storms effect can no longer be regarded as a clear demonstration of four-stage mediation.

Mediation Time

The problem of mediation time, discussed earlier in relation to the *A–B*, *A–B′* paradigm, is equally pertinent to the experiments we have considered under the heading of higher-order mediation. Do mediated transfer effects increase as the response interval is lengthened? This question has been considered primarily in studies of three-stage mediation, with all stages either established or reactivated in the laboratory. The findings have been inconsistent. The length of the response interval failed to influence the amount of transfer in a number of studies (Schwenn & Underwood, 1965; Richardson, 1966b, 1967a; Richardson & Brown, 1966); the expected relation was obtained in others (Schulz & Lovelace, 1964; Richardson, 1967b, 1968b; Schulz &

Weaver, 1968). The explanation proposed by Richardson, that the response interval significantly influences the amount of mediation only when the study time is very short, does not accommodate all the findings. The results reported by Schulz and Weaver bear directly on this hypothesis. In this experiment study time (1.0 versus 2.5 seconds) and response interval (1.5 versus 3.0 seconds) were varied in a factorial design. The amount of mediation, as measured by the difference between an experimental and a control condition, increased significantly with the length of the response interval. Under both conditions an increase in the study interval was more effective when the response interval was long than when it was short; however, the second-order interaction implied by Richardson's hypothesis was not obtained. It is apparent that the time available for mediation can have an important influence on transfer; the exact conditions under which this factor becomes critical remain to be determined.

RETROACTIVE INHIBITION

The first systematic investigation of retroactive inhibition was carried out by Müller and Pilzecker (1900) who are also responsible for naming the phenomenon. They demonstrated poorer retention of a series of nonsense syllables after interpolation of a second series than after a period of rest. Similarity of the successive tasks did not appear to be essential for the occurrence of the effect: The losses were equally great when the subject engaged in describing landscape pictures during the interpolated interval as after the learning of a second list of syllables. The point in the retention interval at which the interpolated activity was introduced was found to be important, the losses being greater when the second task followed 17 seconds after the first rather than 6 minutes later. To account for these findings, Müller and Pilzecker advanced what became known as the perseveration theory of retroactive inhibition. The basic assumption of this theory is that after the end of practice on a given task there is a period of continuing neural activity during which the memory pattern that represents the product of learning is consolidated. The performance of any strenuous task during the period of perseveration interferes with the process of consolidation. Since the level of neural activity diminishes progressively after the end of practice, an immediate interpolated task will be more damaging than a delayed one. The theory also implies that it is the intensity of the interpolated activity that is critical rather than the degree of similarity between the successive tasks. It should be clear that this hypothesis does not view retroactive inhibition as a determinant of long-term forgetting; rather the interfering activity is assumed to increase the susceptibility of the products of learning to forgetting.

Similarity Relations

The finding that dissimilar interpolated activities can produce retroactive inhibition was corroborated in an extensive series of investigations by Heine (1914) in which the study of pictures, lists of numbers, or consonants filled the interval between the acquisition and recall of a series of nonsense syllables. (It may be noted in passing that Heine failed to observe any retroactive effects when retention was measured by recognition rather than recall.) However, the degree of similarity between the original and the interpolated activity remained to be manipulated systematically. This variable soon became a major focus of research on retroactive inhibition (for a review of the early work see Britt, 1936). The factor of similarity assumed theoretical importance because the perseveration hypothesis gradually came to be overshadowed by the conception of retroactive inhibition as a special case of transfer between successive activities. Since transfer is known to depend critically on the similarity relations between tasks, this point of view implied that the same should hold true for retroactive inhibition.
Figure 21.21. The Skaggs-Robinson hypothesis. The theoretical curve shows expected changes in recall as a function of the degree of similarity between the original and the interpolated activity. (Robinson, 1927.)

The Skaggs-Robinson hypothesis A historical landmark in the experimental investigation of the effects of intertask similarity on retroactive inhibition was the Skaggs-Robinson hypothesis. Experiments by Robinson (1920) and Skaggs (1925), in which a wide variety of materials including chess problems, digit series, and paired associates were used, had yielded evidence of greater interference between similar than between dissimilar tasks. Extrapolating from these findings, Robinson formulated the following general law: "As similarity between interpolation and original memorization is reduced from near identity, retention falls away to a minimum and then rises again, but with decreasing similarity it never reaches the level obtaining with maximum similarity" (Robinson, 1927, p. 299). The theoretical function is shown in Figure 21.21. Note that the baseline represents the degree of similarity between activities or tasks rather than between particular components. It soon became apparent that the failure to specify similarity in analytic terms would prove an insuperable obstacle to empirical verification of the hypothesis.

For purposes of testing the law, Robinson (1927) defined similarity in terms of the number of elements common to two series of letters. Instead of using two successive lists, however, he presented to his subject a single series of eight consonants. The first four letters were considered as the original learning task, and the second four letters as the interpolated material. The two halves had either 0, 1, 2, 3, or 4 letters in common; that is, the entire range from complete dissimilarity to identity was represented. Contrary to theoretical expectations, recall dropped steadily as the number of common elements decreased. Harden (1929) speculated that the results obtained by Robinson might represent only the *AB* section of the theoretical
Figure 21.22. The results of three empirical tests of the Skaggs-Robinson hypothesis. Recall is shown for four consonants that appeared in the first half of an eight-item list. In Robinson's experiment the second half of the list also consisted of consonants, with the number of elements in common with the first half varying from four to zero (Positions I through V on the similarity scale). In Harden's experiment the number of digits substituted for consonants in the second half was varied from zero to 4 (Positions V through IX on the similarity scale). Kennelly used the entire range of conditions. (Kennelly, 1941.)

function; in an attempt to extend the range of conditions to the *BC* section, she defined similarity in terms of the number of elements from the same class rather than in terms of identical units. In her experiment the first part of the list consisted of four consonants; in the second part no letter was repeated but either 0, 1, 2, or 3 digits were substituted for consonants. No gradient of recall was obtained, but the most dissimilar condition (four interpolated digits) was superior to the others. Consequently Robinson's and Harden's results together show some agreement with the hypothetical function (Figure 21.22). However, the procedure of combining the functions is questionable in view of the obvious difference in the levels of performance indicated by the discrepancy between the results obtained for the treatment which was common to the two experiments. In a later study by Kennelly (1941) the conditions of both the earlier experiments were included in a single design, As Figure 21.22 shows, Kennelly replicated Robinson's findings but not Harden's, and the theoretical function is clearly not supported. The results are not peculiar to Robinson's method; Kennelly's conclusions remained essentially unchanged when the more conventional procedure of exposing subjects to successive lists was used. Taken together, these studies show little more than the beneficial effects of additional practice when individual elements are repeated.

Another body of data which was viewed as relevant to the Skaggs-Robinson hypothesis came from studies of retroaction in which the successive lists were learned by the method of serial anticipation. In such experiments the similarity between items in the two lists was manipulated in a number of different ways, but no distinction could be made, of course, between the relations existing for stimulus and for response elements. For nonsense materials the degree of similarity was defined in terms of the amount of duplication of letters. This particular manipulation of similarity is complicated, however, by the opportunities for transfer of response learning. Thus, when identical letters occupy the same positions in corresponding syllables, the relation between similarity and interference is quite complex (Cheng, 1929). In the absence of such systematic sources of bias, retroactive inhibition was found to increase substantially with the degree of interlist similarity (Melton & von Lackum, 1941).

In other experiments the similarity between lists was varied with respect to the class of materials as well as to the degree of meaningful relationship between items from the same class. The results showed that retroactive inhibition increased with both types of similarity. Clear support for this conclusion came from a well-known study by McGeoch and McDonald (1931) which encompassed a wide range of similarity relations. The study comprised two experiments. The original list consisted of two-syllable adjectives. In the first experiment five types of interpolated materials were used: either synonyms or antonyms of the original items presented in corresponding serial positions, unrelated adjectives, nonsense syllables of zero percent association value, three-place numbers. These conditions of interpolation represented decreasing degrees of similarity between the classes of materials in the two lists as determined by independent ratings. There were 5 trials of original learning and 10 trials of interpolation. Only the original list was learned in the control condition. The mean numbers of items recalled out of 10 were as follows:

Interpolated learning	*Mean*
None	4.50
Synonyms	1.25
Antonyms	1.83
Unrelated adjectives	2.17
Nonsense syllables	2.58
Numbers	3.68

Retroactive inhibition increases as the classes of materials become more similar. Similarity was, of course, confounded with degree of

interpolated learning since adjectives were learned faster than syllables or numbers. The results cannot, however, be explained on this basis alone since unrelated adjectives were learned better than either synonyms or antonyms but were less interfering than the latter. In McGeoch and McDonald's second experiment adjectives representing three degrees of synonymity to the first-list items were used in interpolated learning. In this case degree of second-list learning did not vary appreciably, but retroactive inhibition again increased with the degree of interlist similarity (see also McGeoch & McGeoch, 1936). The same trend was observed in an experiment by Johnson (1933) in which the learning materials were series of abstract nouns and the conditions of interpolation represented three degrees of synonymity between first-list and second-list items. A later finding reported by Slamecka (1960b) extends the generality of these results. This investigation found that when subjects learn connected discourse (20-word sentences) by the method of serial anticipation, the amount of retroactive inhibition increases with the topical similarity between the original and the interpolated materials.

The studies in which the meaningful similarity of serial lists was varied supported the Skaggs-Robinson hypothesis no more than did those in which the proportion of identical elements was manipulated. In the former interference increased with the degree of similarity, whereas in the latter the trend was in the opposite direction. McGeoch (1942) considered the possibility that the findings for meaningful similarity might represent the *BC* section of the theoretical function; presumably Robinson's results conform to the *AB* section. Clearly, however, the two implied scales of similarity cannot be joined together to yield a single continuum. The mechanisms responsible for the apparently opposite effects of similarity in the two types of experiments are likely to be quite different. In retrospect it becomes apparent that the Skaggs-Robinson hypothesis failed because it was essentially a nonanalytic formulation, which did not specify the locus of intertask similarity. The hypothesis lapsed into disuse as the analysis of similarity relations in retroaction, as in transfer, shifted to the investigation of stimulus and response functions.

Generalization and retroaction (The application of principles of generalization to the analysis of interlist similarity generates parallel predictions for transfer and retroactive effects.) This fact has already become apparent in our discussion of Gibson's hypothesis and of the Osgood surface. The early experimental tests of both these positions were actually carried out in studies of retroaction. As mentioned previously, (the results for transfer and interference were entirely congruent. For paradigms of response identity Hamilton (1943) found increases in retroactive facilitation as stimuli became more similar; with unrelated responses Gibson (1941) obtained complementary increases in retroactive inhibition.) In neither study, however, did the gradient of retroaction clearly support theoretical expectations. (In Osgood's experiments (1946, 1948) there was evidence for reduction in interference as a function of increasing response similarity, particularly when the measures of performance reflected speed of responding.) Again the results fell short of verifying the proposed theoretical gradient. (In the test of the entire surface by Bugelski and Cadwallader (1956) the expected direct relation between degree of stimulus similarity and retroaction was found.) The variations along the response continuum did not agree with the predictions from Osgood's surface; interference was greater when the responses in the successive lists were similar than when they were unrelated or opposed. However, this finding has proved to be quite atypical; the usual finding is that retroactive inhibition increases as the relation between responses changes from a positive degree of meaningful similarity to neutrality (Young, 1955; Kanungo, 1967). In summary, then, although the theoretically

derived gradients were not supported in detail, retroaction, like transfer, is an increasing function of the degree of stimulus similarity; for the range from identity to neutrality the amount of interference decreases as a function of response similarity. However, when response similarity is short of identity, there is little evidence for retroactive facilitation (Haagen, 1943). Further evidence bearing on these conclusions will be presented later when the components of interference for the standard paradigms are considered.

In the experiments mentioned above, response similarity was defined in terms of scaled degrees of synonymity. According to a mediational interpretation it is the degree of associative connection between the items that represents the fundamental underlying variable. This variable has been manipulated directly in some experiments in which measures of retroaction were obtained. McClelland and Heath (1943) compared the *A–B, C–D* and *A–B* and *A′–D* paradigms. In the latter *A′* was the primary normative associate of *A*, whereas *A* and *C* were unrelated words. The amount of retroactive inhibition was greater in the *A′–D* than the *C–D* condition. The fact that interlist intrusions were rare during interpolated learning but frequent in relearning suggests that the effect was unidirectional. However, as Slamecka and Ceraso (1960, p. 458) point out, the original and interpolated stimuli would have to be interchanged before unidirectionality of the interference could be inferred with confidence. The demonstration of unidirectional effects would provide important information about the locus of interference. When the stimuli remain the same, first-list recall is higher when there is a strong associative connection between successive responses than when they are unrelated (Bastian, 1961).

Similarity of environmental context It has long been recognized that the degree of functional similarity between successive tasks depends not only on the manipulated relations between the verbal items but also on the environmental contexts in which the tasks are learned. The standard experimental procedure is for original and interpolated learning to take place in exactly the same laboratory situation. Thus, identity of environmental context constitutes a condition of functional stimulus similarity. To the extent that reponses are associated to the environmental context as well as to the nominal stimulus, an *A–B, A–D* relation obtains between the original and the interpolated habits regardless of the characteristics of the nominal stimuli. It follows that retroactive inhibition should be reduced when original and interpolated learning take place in different environments. While an early test of this prediction by Nagge (1935) was not successful, the expected difference was obtained in an experiment by Bilodeau and Schlosberg (1951). The learning materials were paired adjectives, with half the stimulus terms synonymous in the two lists. The control group learned the original and the interpolated list on the same apparatus and in the same room. Under the experimental treatment the two tasks were presented on different exposure devices and in different rooms; in addition the subject sat while learning one of the lists and stood while learning the other. The test of first-list retention always took place in the same room as the original learning. The amount of retroactive inhibition was found to be substantially smaller in the experimental condition, presumably owing to the discriminative cues provided by the different contexts. These results were confirmed and extended in a subsequent study by Greenspoon and Ranyard (1957). The learning materials were lists of nonsense syllables, with high formal similarity between the first and the second list. The treatments that were compared may be represented as follows, where *A* and *B* refer to different environments and the three successive positions designate the condition of original learning, interpolated learning, and recall, respectively: *AAA, AAB, ABB, ABA*. Retention was highest for *ABA* and poorest

for *AAB*, with *AAA* and *ABB* showing intermediate amounts of loss. This rank order indicates not only a reduction in interference when the successive tasks are practiced in different contexts but also a detrimental effect when recall does not occur in the same context as acquisition.

A recent experiment by Zavortink (1968) suggests that the reductions in interference observed in the earlier studies probably should not be attributed entirely to the effectiveness of differential environmental cues. In this experiment the method of free-recall learning was used. Subjects learned successive lists either in the same situation or in distinctively different ones, with recall tested in the same context as original learning. An additional treatment was, however, added to assess the effect of the disruption produced by the shift from one room to another. After the completion of interpolated learning the subjects in this control condition were sent out of the experimental room on a brief errand; they then returned to the same room to begin the interpolated task. In agreement with the previous findings, the change in environmental context reduced the amount of retroactive inhibition; however, the improvement was equally great for the control group which was disrupted briefly but learned both lists in the same room. A plausible interpretation is that interference is lessened when the successive tasks acquire distinctive "temporal tags" on the basis of which they can be differentiated. A passing disruption as well as a shift in environment can provide the anchor points with respect to which the events can be tagged in temporal order. The possibility remains open, however, that temporal and environmental cues both may be effective.

Degree of Learning

Since retroaction is a consequence of successive practice on different tasks, the magnitude of the effects on retention may be expected to depend on the degree of learning of both the original and the interpolated activity. The basic importance of these variables becomes clearly apparent when intertask interference is considered as a special case of transfer.

Degree of original learning The relation between the degree of original learning and retroactive inhibition has been investigated for lists of numbers (Robinson, 1920), nonsense syllables (McGeoch, 1929; Postman & Riley, 1959), lists of paired adjectives conforming to the *A-B, A-D* paradigm (Briggs, 1957), and connected discourse (Slamecka, 1960a). The common conclusion is that retroactive inhibition is a decreasing function of the degree of original learning. This conclusion holds, however, only for measures of relative interference, that is, the percentages of loss to the base of the control scores. When the trends in absolute differences
Figure 21.23. Retroactive inhibition as a joint function of the degree of original and of interpolated learning. The learning materials were lists of ten paired adjectives. First-list recall is plotted as a function of the number of trials of original learning, with the number of trials of interpolated learning (IL) as the parameter. IL_0 is the control condition. (Data from Briggs, 1957.)

between the experimental and the control groups are considered, the picture is usually quite different. The absolute amounts of interference fail to decline consistently as the degree of original learning increases; in fact, they often rise, especially at high levels of interpolated learning. The results obtained by Briggs (1957) provide a clear illustration of this trend (Figure 21.23); thus, the apparent decline in relative retroactive inhibition is entirely a function of the progressively higher level of performance under the control condition. In that sense the trend in relative measures is an artifact produced by the calculation of percentages to a changing base. The results are clearly contrary to what would be expected if the amount of interference reflected directly the relative strength of the associations in the two lists. The facts indicate that at a given level of interpolated learning there is a certain proportion of first-list items, presumably the *relatively* difficult and weak ones, which is susceptible to interference. This proportion does not decline as the degree of original learning is increased; rather it is likely to become larger because more and more difficult items are mastered during original learning (and hence are recalled by the control group). The assumption that it is the relatively weak items within a list that are most susceptible to retroactive inhibition is supported by the results of an analysis by Runquist (1957).

Degree of interpolated learning The amount of retroactive inhibition is a negatively accelerated increasing function of the degree of interpolated learning. (Since the retention interval in such experiments is usually held constant and the groups to be compared are evaluated against a common control condition, the trends observed for absolute and relative measures have necessarily been congruent.) This function has been obtained for serial lists of nonsense syllables (McGeoch, 1932b; Melton & Irwin, 1940; Postman & Riley, 1959), for lists of paired associates conforming to the *A–B, A–D* paradigm (Thune & Underwood, 1943; Briggs, 1957; Barnes & Underwood, 1959), and for connected discourse (Slamecka, 1960a). The slope of the function is extended, that is, the differential effects of the degree of interpolated learning on retroaction become more pronounced, as the degree of original learning increases. This fact becomes clearly apparent in Figure 21.23. The negative acceleration of the increases in retroactive inhibition deserves special emphasis. There is a substantial amount of interference even when the degree of interpolated learning is clearly lower than that of original learning; and continuing practice on the interpolated task yields diminishing returns.

It was noted earlier that the absolute amount of retroactive inhibition is inversely related to degree of original learning for individual items within a list but that this relation does not hold for a list as a whole. The picture is reversed, as it were, when variations in the degree of interpolated learning are considered. For the total list interference increases with the degree of interpolated learning. Such is not the case, however, for individual items: Under the paradigm of associative interference (*A–B, A–D*) the susceptibility of a first-list association to retroactive interference is independent of the relative strength attained by the corresponding second-list pair (Runquist, 1957). That is, the probability that *A–B* will be lost is not influenced by the degree to which *A–D* is reinforced during a fixed number of interpolated trials. As Runquist points out on the basis of this finding, the laws relating retention to associative strength are not the same when strength is measured within a list and when it is manipulated by varying the number of learning trials.

Amount of interpolation A clear distinction has to be made between the degree and the amount of interpolated learning. The latter refers to the number of different learning units, for example, lists, which are introduced during the retention interval. Retroactive inhibition may be expected to increase directly with the number of interpolated lists. As lists

are added, the amount of time spent on the interpolated activity increases (just as it does with the number of trials on a single interpolated list); moreover, the pool of potentially interfering associations grows larger. The expected progressive increases in retroactive inhibition were obtained in an early study by Twining (1940), in which the learning materials were serial lists of nonsense syllables and the interpolated materials consisted of either 1, 2, 3, 4, or 5 lists. A control experiment showed that the detrimental effects of additional lists could not be attributed to correlated changes in the length of the interval between the end of interpolated learning and the test of recall.

Subsequent experiments were addressed to the question of whether the number of lists per se is an effective variable when the total time devoted to interpolated learning is taken into account. This question was investigated systematically in a study by Underwood (1945). The learning materials were lists of paired adjectives, with the first list (*A–B*) learned to a criterion of 6/10. There were two parallel sets of experimental treatments representing conditions of single-list and multiple-list interpolation, respectively. The single interpolated list (*A–D*) was practiced for either 8, 16, or 24 trials. The corresponding multiple-interpolation groups learned either 2, 4, or 6 lists (*A–D, A–E,* and so on) for 4 trials each. The amount of retroactive inhibition increased progressively with the number of interpolated lists; at the higher levels of practice, multiple lists produced more interference than a single list. Since the critical comparisons were between groups that had received exactly the same numbers of learning trials, the sheer amount of time spent on the interpolated activity cannot be responsible for the differences.

This conclusion was supported by the results of a later study by Postman (1965) in which all groups received exactly the same number of interpolated trials but the number of lists over which these trials were distributed was varied. Thus, interpolated practice was either for 16 trials on a single list, for 8 trials each on two lists, or for 4 trials each on four lists. The *A–D* paradigm of transfer was again used, with trigrams as stimuli and adjectives as responses. An unpaced test of recall showed steady increases in retroactive inhibition as a function of the number of interpolated lists (see also Howe, 1967; Birnbaum, 1968).

While it is possible to rule out the sheer duration of interpolated learning as an explanatory factor, the observed differences between single and multiple interpolation continue to pose complex problems of interpretation. When duration of interpolated practice is held constant, changes in the number of lists inevitably entail variations in the degree of learning for individual units. The associations in a single list learned for 16 trials reach a high level of strength; those in the four successive lists learned for four trials each remain relatively weak. Thus, two potentially important determinants of interference vary together: the number and the strength of the interfering associations. Since retroactive inhibition in general increases with the degree of interpolated learning, and yet multiple sets of weak associations produce more interference than a single set of strong ones, one may be led to the conclusion that the number of interfering associations is the overriding factor. It must be borne in mind, however, that the function relating retroactive inhibition to the degree of interpolated learning shows pronounced negative acceleration. Thus, there is little or no buildup of interference once practice on a single list reaches the stage of overlearning. On the other hand, the processes responsible for retroaction may be reactivated each time the acquisition of a new list is begun. We shall return to this problem in our discussion of unlearning.

Theories of Retroactive Inhibition

McGeoch's theory of reproductive inhibition Modern accounts of interference processes in retention represent a line of development that has its origin in McGeoch's theoretical analysis of retroactive inhibition
